In adults, maximum blood concentration correlates with dose. The minimal effective serum concentration for seizure control is 3 μg/mL. Peak therapeutic serum concentrations of 10 to 63 μg/mL occur 1 hour after dose. Trough therapeutic concentrations occurring just before the next dose range from 3 to 34 μg/mL.[8]

Toxicity effects known to be associated with levetiracetam use include decreased RBC count and hematocrit, decreased neutrophil count, somnolence, asthenia, and dizziness. These toxicities may be associated with blood concentrations in the therapeutic range. Co-administration of cimetidine will interfere with the test, producing artifactually increased measurements of levetiracetam. The laboratory can identify the presence of cimetidine, and laboratory reports will reflect cimetidine interference if it is detected.

Oxcarbazepine

Oxcarbazepine (OCBZ—*Trileptal*) has been approved for therapy of partial seizures with and without secondarily generalized seizures in adults and as adjunctive therapy for partial onset seizures in children ages 4 to 16. OCBZ is a prodrug that is almost immediately and completely metabolized to 10-hydroxy-10,11-dihydrocarbamazepine known as monohydroxycarbamazepine (MHC), the metabolite responsible for OCBZ's therapeutic effect. Reductase enzymes not subject to induction catalyze the conversion of OCBZ to MHC. MHC is cleared as the glucuronide conjugate formed by action of UGT. MHC selectively induces CyP 3A4 enzymes responsible for the metabolism of estrogens, immunosuppressants, and the dihydropyridine calcium-channel blockers. Carbamazepine activates UGT, enhancing the rate of clearance of MHC.

The metabolism of OCBZ is extensive; about 96% of the dose is excreted in the urine as metabolites, less than 1% as unchanged drug, and about 27% as free MHC. The majority of the dose is recovered as the glucuronide ester of either OCBZ or MHC, approximately 9% and 49%, respectively. The apparent volume of distribution of MHC is 0.8 L/kg. Approximately 40% of MHC is bound to serum proteins, predominantly to albumin. The elimination half-life is 1.0 to 2.5 hours for OCBZ and 8 to 10 hours for MHC. MHC shows a linear and dose-proportional increase (based on OCBZ dose) in the range of 300 to 2700 mg/day. Since MHC is cleared predominantly by the kidney, the daily dosage of OCBZ given to patients with creatinine clearance <30 mL/min should be half that given to patients with normal renal function.[45]

Steady-state MHC concentrations in a trough specimen collected just before the next dose correlate with the OCBZ dose. Trough monitoring is recommended for assessment of compliance or to verify dose adequacy. Optimal response to OCBZ occurs when trough MHC concentration is in the range of 6 to 10 μg/mL.[45] Peak plasma concentration of MHC occurs 4 to 6 hours after dose. Because carbamazepine activates UGT, patients taking carbamazepine concomitantly with OCBZ have significantly lower MHC concentrations than patients not receiving carbamazepine. Toxicity effects associated with OCBZ includes hyponatremia, dizziness, somnolence, diplopia, fatigue, nausea, vomiting, ataxia, abnormal vision, abdominal pain, tremor, dyspepsia, and abnormal gait. These toxicities may be observed when blood concentrations are in the therapeutic range. Serum sodium concentration below 125 mmol/L and decreased T4 have been seen in patients treated with MHC.

Phenobarbital

Phenobarbital is used in the treatment of all seizures except absence seizures, and is known by a wide variety of proprietary names and found in combination with many other drugs. It is used for treatment of generalized tonic-clonic, partial, focal motor, temporal lobe, and febrile seizures. It is also known to reduce synaptic transmission, resulting in decreased excitability of the entire nerve cell, inducing sedation. Phenobarbital potentiates synaptic inhibition through action on the γ-aminobutyric acid-A ($GABA_A$) receptor by increasing the duration of chloride flow into the synapse.[52] The end result is an increase in seizure threshold and inhibition of the spread of discharges from the epileptic foci.

Absorption of oral phenobarbital is slow but complete. The time at which peak plasma concentrations are reached is widely variable and ranges from 4 to 10 hours after the dose. Phenobarbital is 40% to 60% bound to plasma proteins. CyP 2C19 is the primary hepatic enzyme involved in metabolism, producing an elimination half-life of 70 to 100 hours; metabolism is age dependent (children average 70 hours, geriatric patients 100 hours). Because hepatic metabolism is the primary organ of elimination, reduced liver function results in prolonged half-life.

The optimally effective therapeutic concentration of phenobarbital is between 15 and 40 μg/mL.[35] The predominant side effect observed in adults at blood concentrations greater than 40 μg/mL is sedation, although tolerance to this effect develops with chronic therapy.

Phenobarbital is metabolized by CyP 2C19 to *p*-hydroxyphenobarbital, which is largely excreted as the glucuronide (by UGT). When renal and hepatic function are decreased, patients experience decreased clearance of the drug. Alcohol, carbamazepine, other barbiturates, and rifampin induce oxidative enzymes (CyP 2C19 and 2C9); this induction results in increased metabolism of phenytoin, reduced serum concentration of phenobarbital, and a reduced pharmaco-

logical effect. Drugs such as chloramphenicol, cimetidine, disulfiram, isoniazid, omeprazole, and topiramate compete with phenobarbital metabolism. Elimination of phenobarbital may be decreased in the presence of valproic acid and salicylate if reduction in urinary pH occurs. During chronic administration of either valproate or salicylate, the concentration of phenobarbital may increase 10% to 20%, and a dose adjustment may be necessary to avoid intoxication. Phenobarbital induces mixed-function oxidative enzymes (CyP 2B6), resulting in increased metabolism of other xenobiotics after approximately 1 to 2 weeks of therapy.

Because of the long elimination half-life of phenobarbital, the blood concentration does not change rapidly. Therefore a serum specimen collected late in the dose interval (trough) is representative of the overall effect. Results from specimens collected 2 to 4 hours after the dose can be misleading, because they may be construed to be the peak concentration when in actuality they precede the peak. Table 33-1 summarizes pharmacokinetic data of the anticonvulsant drugs.

Phenytoin

Phenytoin (diphenylhydantoin), most commonly available as *Dilantin* but also available in generic form, is used in the treatment of primary or secondary generalized tonic-clonic seizures, partial or complex-partial seizures, and status epilepticus. The drug is not effective for absence seizures. Phenytoin acts by modulating the synaptic sodium channel by prolonging inactivation, which reduces the ability of the neuron to respond at high frequency.[51] The physiological effect of this action is reduction in central synaptic transmission, aiding in control of abnormal neuronal excitability.

Phenytoin is not readily soluble in aqueous solutions. When administered by intramuscular injection, most of the dose precipitates at the site of injection and is then slowly absorbed. A prodrug called fosphenytoin *(Cerebyx)* allows intramuscular injection of phenytoin and has increased aqueous solubility for intramuscular injection.[112] After injection, it is rapidly converted to phenytoin. Absorption of oral phenytoin is slow and sometimes incomplete. Variations in the drug preparation have been blamed for low bioavailability. Once absorbed, the drug is tightly bound to protein (90% to 95%). As with all drugs, the pharmacological effect of phenytoin is directly related to the amount present in the free (unbound) state. Only free phenytoin is available to cross biological membranes and interact at biologically important binding sites. The degree of protein binding can be reduced by the presence of other drugs, anemia, and hypoalbuminemia, which occurs regularly in the elderly. In these conditions, an increased effect is observed at the same total drug concentration as in plasma from normal patients.

The optimal therapeutic concentration for seizure control without side effects is 10 to 20 μg/mL. In a large population study, Buchthal and colleagues found a 50% response rate in patients with plasma concentrations greater than 10 μg/mL and an 86% suppression of seizure activity at concentrations exceeding 15 μg/mL.[12] These concentrations also serve as reasonable guidelines when the drug is used as a cardiac antiarrhythmic agent. Free phenytoin concentrations of 1 to 2 μg/mL are optimal. Total phenytoin concentrations in excess of 20 μg/mL do not usually enhance seizure control and are often associated with nystagmus and ataxia. Total phenytoin plasma concentrations in excess of 35 μg/mL have been shown to actually precipitate seizure activity. A side effect of phenytoin not related to plasma concentration is development of gingival hyperplasia.

Phenytoin is metabolized by hepatic microsomal hydroxylating enzymes by CyP 2C19 and 2C9. The principal metabolite is 5-(*p*-hydroxyphenyl)-5-phenylhydantoin, which is excreted principally as a glucuronide ester (by UGT). Other minor metabolites are of minimal clinical importance. Hepatic metabolism of phenytoin may become saturated within the therapeutic range. Once metabolism is saturated, small dose increments result in large changes in blood concentration (see Figure 33-10); this phenomenon partially explains the wide variation in dose among patients that is required to accomplish a therapeutic effect.[66] Because of this saturation phenomenon, first-order kinetics do not apply to phenytoin at blood concentrations in excess of 5 μg/mL.

The time to collect the specimen is determined by the reason for monitoring. If a patient displays any symptoms of intoxication, then the peak blood concentration is of interest. This specimen is collected 4 to 5 hours after the dose, although the peak level may be delayed up to 8 hours if the drug is given in conjunction with food or drugs that increase stomach acidity. If the principal question at hand is adequate therapy, then the trough concentration is more useful; that specimen is collected just before the next dose is given.

A number of drug interactions result in alteration of the disposition of phenytoin. Alcohol, carbamazepine, other barbiturates, and rifampin induce oxidative enzymes (CyP 2C19 and 2C9); this induction results in increased metabolism of phenytoin, reduced serum concentration of both total and free phenytoin, and reduced pharmacological effect. Drugs such as chloramphenicol, cimetidine, disulfiram, isoniazid, omeprazole, and topiramate compete with phenytoin metabolism, resulting in an increase of both total and free phenytoin concentrations and enhancement of the pharmacological effect. Salicylate, valproic acid, phenylbutazone, sulfisoxazole, and sulfonylureas compete with phenytoin for serum protein-binding sites. The end result is diminished total serum concentration of phenytoin while the free phenytoin concentration and pharmacological effect remain approximately the same. The interest in monitoring the free phenytoin concentration is in response to these altered protein-binding states.

Primidone

Primidone, proprietary name *Mysoline,* is effective in the treatment of tonic-clonic and partial seizures. The mecha-

nism of action of this drug is similar to that described for phenobarbital, and the therapeutic effect is due partially to the accumulation of its major metabolite, phenobarbital, created by the action of CyP 2C19. A second metabolite of primidone, phenylethylmalonamide, created by the action of CyP 2C9 also has some antiepileptic activity.

Primidone is rapidly and completely absorbed after oral administration. Once absorbed, it is not highly protein bound and it has a half-life of approximately 10 hours. Disposition of the drug is known to be affected by the drugs that alter CyP 2C19 and 2C9 metabolism and by diseases that alter phenobarbital disposition.

The optimal therapeutic concentration of primidone has been established as 5 to 12 μg/mL. Because phenobarbital is an active metabolite of primidone, concurrent analysis of phenobarbital is required for complete result interpretation. The previously defined therapeutic range for phenobarbital applies to adequate primidone therapy. The phenobarbital concentrations rise gradually over a period of 1 to 2 weeks after therapy is initiated. Toxicity due to accumulation of primidone occurs at serum concentrations in excess of 15 μg/mL and is usually associated with symptoms of sedation, nausea, vomiting, diplopia, dizziness, ataxia, and a phenobarbital concentration greater than 40 μg/mL. Specimen collection is dictated by the same rules that apply to phenobarbital; the trough concentration is most useful.

Co-administration of acetazolamide with primidone results in decreased gastrointestinal absorption of primidone and subsequent diminished plasma concentrations. Primidone administered in association with phenytoin produces a modest elevation of the phenobarbital/primidone ratio because phenytoin competes with the hepatic hydroxylating enzymes associated with phenobarbital's metabolism. Co-administration of valproic acid, for the same reasons outlined for phenobarbital, causes a modest increase in both primidone and phenobarbital serum concentrations.

Topiramate

Topiramate *(Topamax)* is a broad spectrum, antiepileptic drug. It has sodium channel blocking activity and it potentiates the activity of gamma-aminobutyric acid (GABA), and inhibits the potentiation of the glutamate receptor. Because of this range of activities, topiramate blocks seizure spread rather than raising seizure potential.

Topiramate is routinely administered orally, absorbed rapidly, and metabolized minimally, but its disposition is affected by CyP 2C19. Serum concentrations of other anticonvulsant drugs are not significantly affected by the concurrent administration of topiramate, with the exception in individual patients on phenytoin who exhibit increased phenytoin plasma concentrations after addition of topiramate. Co-administration of phenytoin or carbamazepine decreases topiramate serum concentrations. Changes in cotherapy with phenytoin or carbamazepine (e.g., addition or withdrawal) for patients stabilized on topiramate therapy may require topiramate dose adjustment. As with other renally eliminated anticonvulsant drugs, patients with impaired renal function exhibit decreased renal clearance.

Peak serum blood concentration of topiramate is achieved 2 to 3 hours after dosing. Peak concentrations in the range of 9.0 to 12 μg/mL indicate that the dose is appropriate to achieve optimal antiepileptic activity. The minimum blood concentration, achieved just before the next dose, should be >2.0 μg/mL to ensure adequate antiepileptic protection. Concentrations <2.0 μg/mL indicate that the dose is either suboptimal or administered too infrequently.[103] Topiramate may be quantified by immunoassay or GLC-FID.

Valproic Acid

Valproic acid, brand name *Depakene* or *Depakote*, is used for treatment of absence seizures. It has also been shown to be useful against tonic-clonic and partial seizures when used in conjunction with other antiepileptic agents, such as phenobarbital or phenytoin. The drug inhibits the enzyme GABA transaminase, resulting in an increase in the concentration of GABA in the brain. GABA is a potent inhibitor of presynaptic and postsynaptic discharges in the central nervous system. Valproic acid also modulates the synaptic sodium channel by prolonging inactivation, which reduces the ability of the neuron to respond at high frequency. This action gives it some activity against tonic-clonic seizures.[51]

Valproic acid is rapidly and almost completely absorbed after oral administration. Peak concentrations occur 1 to 4 hours after an oral dose. The principal metabolite, 2-*n*-propyl-3-ketopentanoic acid, is created by action of CyP 2C19 and has anticonvulsant activity comparable to that of valproic acid, although this metabolite does not accumulate in plasma; the exact cytochrome enzyme isomer involved in metabolism has not been identified. The single-dose half-life is 16 hours in healthy adults, but this decreases to 12 hours on chronic therapy and may be as short as 8 hours in children. In neonates and in hepatic disease, when metabolism is reduced, the half-life becomes prolonged. Valproic acid is highly protein bound (93%). In circumstances when competition for protein binding increases, such as in uremia, cirrhosis, or concurrent drug therapy, the percent of free valproic acid increases.

The minimum effective therapeutic concentration of valproic acid is 50 μg/mL. Concentrations in excess of 100 μg/mL have been associated with hepatic toxicity and acute toxic encephalopathy. Glycine has been observed to accumulate in patients on valproic acid therapy.

Clearance of valproic acid is rapid, presenting a dosing dilemma. The dose must be adequate to provide a plasma concentration >40 μg/mL while avoiding concentrations in excess of 100 μg/mL. The ideal specimen for monitoring blood concentration is the one drawn just before the next dose, usually early in the morning to confirm that an adequate dose has been prescribed before bedtime. Dosing is particularly problematic in young children who might sleep for more than one complete half-life of the drug.

Valproic acid modulates the action of various other common antiepileptic drugs. It inhibits the nonrenal clearance of phenobarbital, resulting in elevated phenobarbital levels. It competes with phenytoin for protein-binding sites. The free phenytoin concentration remains approximately the same, but the total phenytoin in the plasma decreases. Because the free phenytoin concentration remains unchanged, the pharmacological effect is retained. Other common antiepileptic drugs that induce hepatic oxidative enzymes result in increased valproic acid clearance; this increased clearance rate requires a higher dose to maintain effective therapeutic levels.

γ-Aminobutyric Acid Analogs/Agonists

Studies of benzodiazepines that occurred in the 1970s led to knowledge of the GABA receptor, a membrane-bound protein complex on the surface of dedicated neural and glial cells that operate as inhibitory neurotransmitters. Activation of these cells serves to restrain neuronal excitation. Absence of or decreased GABA control of neurotransmission is one cause of seizure activity. These studies led to the development of drugs that act to increase the activity of GABA receptors, either by increasing GABA concentration or by directly interacting with the GABA receptor. Felbamate, gabapentin, lamotrigine, tiagabine, and zonisamide are examples of such drugs.

Felbamate

Felbamate, proprietary name *Felbatol,* was approved for primary or adjunctive therapy of partial seizures. Its use is limited to those patients who fail other drug treatments, because felbamate carries with it a substantial risk of aplastic anemia and liver failure that is not related to the blood level. Biweekly monitoring of complete blood count, serum aminotransferases, and bilirubin is recommended to detect early onset of these side effects. Felbamate is particularly effective in control of Lennox-Gastaut syndrome.

Felbamate is completely absorbed from the gastrointestinal tract. The drug is 30% bound to plasma proteins, and optimal blood concentrations for felbamate range from 40 to 120 μg/mL.[26] It is eliminated by hepatic metabolism (CyP 2D6), with its half-life ranging from 14 to 21 hours.[26] Felbamate saturates metabolism when the concentration exceeds 120 μg/mL; at that concentration, metabolism converts from first order to zero order. HPLC is commonly used for felbamate analysis.[116,128]

Gabapentin

Gabapentin, proprietary name *Neurontin,* is a chemical analog of GABA that promotes the release of GABA. It does not interact directly with the GABA receptor, nor does it inhibit glutamic acid decarboxylase, the enzyme that usually controls cellular concentration of GABA. Gabapentin has been proven effective for treatment of drug-resistant partial seizures.[113]

Absorption of oral gabapentin is complete. Gabapentin is 10% bound to plasma proteins, and its elimination half-life is 5 to 9 hours. The optimally effective therapeutic concentration of gabapentin is between 2 and 12 μg/mL.[10,26] Side effects observed in adults at blood concentrations greater than 12 μg/mL are somnolence, ataxia, dizziness, and fatigue. The drug does not undergo hepatic metabolism, and it does not activate any metabolic enzymes, so co-administration of gabapentin with other drugs does not affect their concentrations. Co-administration with antacids is known to reduce absorption of gabapentin by approximately 20%. HPLC is used to quantify gabapentin.[53]

Lamotrigine

Lamotrigine, proprietary name *Lamictal,* is not a GABA analog, but binds to the GABA receptor; it is therefore considered a GABA agonist. Lamotrigine acts like phenytoin and carbamazepine, blocking repetitive nerve firings induced by depolarization of spinal cord neurons. The FDA approved lamotrigine for adjunctive therapy of partial seizures.

Lamotrigine is satisfactorily tolerated and completely absorbed from the gastrointestinal tract after oral administration. It is 60% bound to plasma proteins. Optimal response occurs when the trough blood level is between 1 and 2 μg/mL, and the peak level ranges from 5 to 8 μg/mL.[18,26] Half-life ranges from 20 to 30 hours. Elimination occurs through metabolism by UGT; the metabolite is the glucuronide ester. Co-administration with CyP 2C19–inducing drugs such as phenobarbital, phenytoin, or carbamazepine results in reduced lamotrigine concentration—dosage increases of approximately 30% are required to maintain optimal blood concentration.

Lamotrigine is a potent inhibitor of dihydrofolate reductase. Folate concentrations are decreased when this drug is administered. If folate replacement is not implemented, rash and anemia may be experienced when lamotrigine is at its therapeutic concentration. Lamotrigine has also been associated with development of severe rash (Stevens-Johnson syndrome) in approximately 1% of patients receiving lamotrigine. These side effects are not drug concentration related.

Dizziness, ataxia, diplopia, blurred vision, nausea, and vomiting are signs of toxicity that occur when the blood level exceeds 10 μg/mL. A chromatographic method for analysis of lamotrigine has been reported.[42]

Tiagabine

Tiagabine, proprietary name *Gabitril,* is indicated as adjunctive therapy in adults and children for treatment of partial seizures. It is frequently administered to patients receiving at least one concomitant antiepileptic drug. Tiagabine is a selective blocker of GABA uptake into presynaptic neurons. Tiagabine binds to recognition sites associated with the GABA uptake carrier. By this action, tiagabine blocks GABA uptake into presynaptic neurons, permitting more GABA to

be available for receptor binding on the surface of postsynaptic cells.

Tiagabine has an elimination half-life of 7 to 9 hours. In patients receiving CyP 3A4 inducing anti-epileptic drugs (AEDs), the elimination half-life decreases to 4 to 7 hours. Phenytoin, phenobarbital, and carbamazepine are CyP 3A4 inducers. Valproic acid and gabapentin are not. Tiagabine is not considered to be a CyP 3A4 inducer.[130]

Tiagabine reaches peak serum concentration approximately 45 minutes following an oral dose in the fasting state. Pediatric patients reach peak concentration at approximately 2.4 hours.[49] Tiagabine is well absorbed, with food slowing the absorption rate but not altering the extent of absorption (high fat diet prolongs peak serum concentrations to about 2.5 hours). Tiagabine is >95% absorbed, with oral bioavailability of about 90%. Tiagabine pharmacokinetics are linear over the typical dose range of 2 to 24 mg. Tiagabine is 96% bound to human plasma proteins, mainly to serum albumin and alpha-1-acid glycoprotein. Co-administration with valproic acid reduces protein binding to 94%, increasing the free fraction of tiagabine by 40%.[8]

Trough tiagabine serum concentrations vary from 5 to 35 ng/mL in most patients receiving therapeutic doses and are proportional to dose. A single 4 mg dose administered to a child produced a peak serum concentration in the range of 52 to 108 ng/mL. At steady state, an adult receiving 40 mg per day is expected to have peak serum concentration in the range of 110 to 260 ng/mL, and an adult receiving 80 mg per day is expected to have peak serum concentration in the range of 220 to 520 ng/mL. Serum concentrations >800 ng/mL indicate excessive dosing associated with adverse effects such as asthenia, ataxia, difficulty concentrating, and depression.

Zonisamide

Zonisamide, proprietary name *Zonegran,* is a sodium and calcium channel blocker. It also binds to the GABA receptor, but does not produce a chloride influx. Approved for adjunct treatment of partial seizures that do not respond to a single drug, zonisamide is satisfactorily tolerated but not completely absorbed from the gastrointestinal tract after oral administration; bioavailability averages 50%. It is 50% bound to plasma proteins. Optimal response occurs when the peak level ranged from 10 to 30 μg/mL.[72] Half-life ranges from 50 to 70 hours. Elimination occurs through metabolism by Cyp 2C19. Co-administration with CyP 2C19–inducing drugs such as phenobarbital, phenytoin, or carbamazepine results in reduced zonisamide concentration.[40] Chromatographic methods for analysis of zonisamide have been reported.[61,94]

Miscellaneous, Infrequently Used Antiepileptic Drugs

Benzodiazepines, mephobarbital, and succinimides have antiepileptic activity. However, they are infrequently prescribed for this purpose.

Benzodiazepines

Benzodiazepines interact at the $GABA_A$ receptor to increase the duration of chloride flow into the synapse.[51] The end result is an increase in seizure threshold and inhibition of the spread of discharges from the epileptic foci.

Diazepam, proprietary name *Valium,* is frequently used in emergency situations to gain control in status epilepticus. Unfortunately, tolerance to diazepam at the GABA receptor develops rapidly, and diazepam becomes ineffective within 2 to 3 days. Diazepam is therefore not used for long-term control of seizure disorders.

Clonazepam, proprietary name *Clonopin,* is a benzodiazepine with chemical structure closely related to diazepam. The mechanism of action is the same as described for diazepam, but tolerance does not develop as rapidly as with diazepam. Clonazepam is currently approved for use in absence seizures, infantile spasms, akinetic seizures, and Lennox-Gastaut syndrome. Plasma concentrations associated with maximal effectiveness of the drug range from 15 to 60 ng/mL. At concentrations higher than 80 ng/mL, no additional seizure protection is observed, and toxicity (drowsiness and ataxia) ensues. The most suitable methods adaptable to routine analysis are based on GLC with electron capture detection,[30] although HPLC methods also are effective.[1]

Mephobarbital

The antiepileptic activity of mephobarbital, proprietary name *Mebaral,* is due to its principal metabolite, phenobarbital. Metabolism is through hepatic CyP 2C19, induced by phenobarbital. Thus long-term therapy results in multiphasic elimination profiles of the drug. Early in therapy, high concentrations (>5 μg/mL) of mephobarbital and low concentrations (<10 μg/mL) of phenobarbital may be observed. After enzymatic induction, the pattern shifts to one in which phenobarbital predominates (20 to 40 μg/mL) and mephobarbital is a minor constituent (1 to 3 μg/mL) at equilibrium. Effective therapeutic monitoring can be accomplished only after a steady state has been achieved by administering a constant dose for at least 21 days. Mephobarbital concentration is usually determined by chromatography as described for phenobarbital methods. It should be noted that mephobarbital in most immunoassays cross-reacts to some degree with phenobarbital.

Succinimides

Three succinimides have proved useful in the control of absence seizures: ethosuximide (proprietary name *Zarontin*), methsuximide (proprietary name *Celontin*), and phensuximide (proprietary name *Milontin*). Ethosuximide is widely used and is reviewed elsewhere in this chapter. Methsuximide and phensuximide are less commonly used and monitored.

Both methsuximide and phensuximide are active in control of absence seizures and seizures of temporal lobe

TABLE 33-2 Pharmacokinetic Parameters of Cardioactive Drugs

Drug	Minimum Effective Concentration (MEC) (μg/mL*)	Minimum Toxic Concentration (MTC) (μg/mL*)	Average Half-Life (hr)	Average Oral Volume of Distribution (L/kg)	Average Bioavailability (%)	Important Protein Binding (%)	Metabolizing Enzymes
Amiodarone	1.0	2.0	45 days†	60	45	99	CyP 3A4, Pg
Digoxin	0.5 ng/mL*	0.8 ng/mL*	40	5	70	25	CyP 3A4, Pg

*Except where noted in text.
†See text.

origin, but phensuximide has been found to be less effective because of its short half-life. Methsuximide is effective because it is metabolized to an active metabolite that is stable and has a long half-life. Steady-state serum concentrations of methsuximide and normethsuximide on a standard adult dose of 900 mg/d range from 0.01 to 0.040 μg/mL and 10 to 40 μg/mL, respectively.

Cardioactive Drugs

Pharmacokinetic parameters of digoxin and other cardioactive drugs are summarized in Table 33-2. Digoxin, disopyramide, lidocaine, procainamide, and quinidine are usually quantified by immunoassay. HPLC methods to quantify the other cardioactive drugs are reviewed in a previous edition of this chapter.[91]

Amiodarone

Amiodarone, proprietary name *Cordarone,* is used to control supraventricular and ventricular tachyarrhythmias. The drug is of interest as a substitute for other class I antiarrhythmics, such as procainamide or quinidine, because it has a very long elimination half-life (45 days). The effective serum concentration of the drug, measured 24 hours after a single daily dose, ranges from 1.0 to 2.0 μg/mL.[117] The drug is indicated for control of ventricular tachycardia and fibrillation resistant to other forms of therapy. Amiodarone is extensively metabolized by the CyP 3A4 system; its metabolism is significantly affected by co-administration with carbamazepine, erythromycin, phenytoin, rifampin, and St. John's Wort. In addition, the presence of amiodarone will prolong metabolism of several drugs including cyclosporine, digoxin, protease inhibitors, sirolimus (Siro), tacrolimus (Tac), and verapamil.

Amiodarone is a structural analog of thyroxine, and much of its toxicity is related to interactions that occur at thyroid hormone receptors. Pulmonary fibrosis is a frequent adverse effect that is related to dose, and drug level doses <200 mg/day and maintenance of peak levels <2 μg/mL can help avoid this life-threatening side effect.

Digoxin

Digoxin, proprietary name *Lanoxin,* is one of a group of cardiac glycosides obtained from digitalis plants (e.g., *Digitalis lanata*). It restores the force of cardiac contraction in congestive heart failure and is also used in the management of supraventricular tachycardias. The drug binds to the extracytoplasmic side of the α-subunit of membrane-bound Na^+-K^+-ATPase, inhibiting both cellular Na^+ efflux, and K^+ influx in myocardial cells. This reduces the sodium/potassium gradient in the Purkinje's fibers of the atrial, junctional, and ventricular myocardium, resulting in a decreased transmembrane potential. Inhibition of Na^+-K^+-ATPase is postulated to enhance movement of calcium ions in the cell, increasing calcium ion availability and improving cardiac contractility.

At low concentrations, digoxin causes the atrium to be less electrically excitable. Moderate concentrations of digoxin are required to reduce the rate of depolarization in the spontaneously depolarizing conductive fibers (Purkinje's fibers), and toxic concentrations of digoxin are necessary to diminish depolarization of the ventricular myocardium. Disagreement over the clinical value of digoxin measurements and the failure of the digoxin concentration to correlate with clinical toxicity are usually related to aberrations in serum and tissue concentrations of sodium, potassium, magnesium, and calcium. Increased sensitivity to digoxin is

noted in states of hypokalemia, hypomagnesemia, and hypercalcemia, which make establishment of the true therapeutic concentration of digoxin difficult because all parameters are interactive.

Absorption of digoxin is variable and dependent on the drug formulation. The *U.S. Pharmacopeia* requires more than 65% of digoxin in tablet form to dissolve in 60 minutes. In plasma, digoxin is 25% protein bound. Digoxin is concentrated in tissue. In a steady state, the concentration of digoxin in cardiac tissue is 15 to 30 times that of plasma. Accumulation of digoxin in tissue lags behind the plasma concentration. For example, although the peak plasma concentration is reached 2 to 3 hours after the oral dose, the peak tissue concentration occurs 6 to 10 hours after an oral dose. Although pharmacological effects and toxicity correlate with tissue concentration rather than plasma concentration, the effective and safe therapeutic plasma concentration of digoxin ranges from 0.8 to 2.0 ng/mL.[102] (However, this range has recently been questioned, with a suggestion that maintenance of digoxin in the range of 0.5 to 0.8 ng/mL is most efficacious.)[114] Clinically, the effective range for digoxin is not determined at the peak plasma concentration but rather at the time of peak tissue concentration. Thus to ensure a correlation between plasma concentration and tissue concentration, the appropriate time to collect the specimen is 8 hours or more after the dose. Results from specimens collected earlier than 8 hours after the dose are misleading, because they do not correlate with tissue concentrations.

Digoxin *toxicity* is characterized by nonspecific symptoms of nausea, vomiting, anorexia, and predominance of green/yellow visual distortion. Cardiac symptoms of intoxication include multiform premature ventricular contractions (PVCs), ventricular bigeminy, ventricular tachycardia, and ventricular fibrillation. Combinations of decreased conduction and increased automaticity may result in paroxysmal atrial tachycardia with atrioventricular node block and nonparoxysmal junction tachycardia. These symptoms are frequently observed when the blood concentration exceeds 2 ng/mL in adults. Children tolerate higher concentrations and do not usually exhibit toxicity until the digoxin concentration exceeds 4 ng/mL. The relationship between the blood level of digoxin and clinical and toxic response is presented in Figure 33-11.[74]

Elimination of digoxin follows first-order kinetics; 50% to 70% is excreted unchanged or in the form of digoxigenin monosaccharides or disaccharides in the urine. A small amount is metabolized to dihydrodigoxin and also excreted by the kidneys. The remainder is found in the stool as digoxigenin and its saccharides. As a result, digoxin toxicity develops more frequently and lasts longer in patients with renal impairment. Dose requirements are decreased in patients with renal disease. In 1979, Bresnahan and Vlietstra presented a simple method for calculating dosage based on creatinine clearance and uses the concepts outlined in equation (13).[11] Digoxin is metabolized by CyP 3A4 and is transported out of cells via the P-glycoprotein transporter (Pg); co-

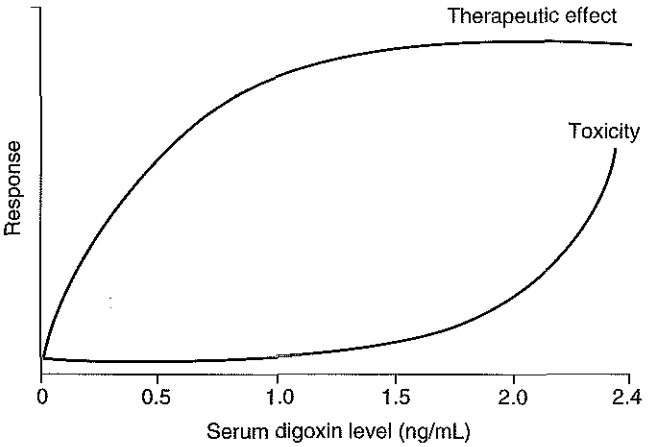

Figure 33-11 Relationship between digoxin concentration and response, showing that the therapeutic effect occurs at low concentration, whereas the onset of toxicity occurs exponentially as the concentration increases.

administration of cyclosporine, protease inhibitors, quinidine, Siro, Tac, or verapamil prolongs the rate of clearance of digoxin, requiring dose adjustment.

Decreased gastrointestinal absorption of digoxin occurs with sprue and small intestinal resections, high-fiber diets, hyperthyroidism, and situations of increased gastrointestinal motility. A more dangerous situation develops secondary to the interaction of quinidine and digoxin,[70] resulting in an increase in the digoxin concentration.

Nonisotopic immunoassays (see Chapter 9) are the standard for measuring and monitoring digoxin levels. Accurate results have been obtained with small sample sizes (e.g., 10 to 50 µL serum) and short incubation times (e.g., 8 to 30 minutes). In the typical immunoassay, patient samples, controls, and calibrators containing digoxin are placed in assay tubes with a constant amount of immobilized digoxin antibody. During an incubation period, the digoxin from the specimen binds to the antibodies. In most assays, the remaining unbound digoxin antibodies left after the preliminary incubation are washed and then reacted with a labeled digoxin analog followed by a short, fixed-time incubation. The amount of label bound to the immobilized antibody decreases in proportion to the increasing amounts of unlabeled digoxin from the original specimen. Levels of digoxin in the samples are then determined by relating the amount of bound label in each tube to a calibration curve constructed from appropriate calibrators. For more detailed instructions on these techniques, the protocol for the specific procedure used should be consulted.

Note: Digitoxin is infrequently prescribed; however, serum levels should be evaluated in patients suspected of having digitalis intoxication with nondetectable digoxin levels. Digoxin immunoassay procedures cross-react only minimally with digitoxin, requiring that a digitoxin-selective antibody be substituted in the assay.

Disopyramide

Disopyramide, proprietary name *Norpace,* is used for maintenance of sinus rhythm in patients with atrial flutter and atrial fibrillation and for prevention of ventricular tachycardia and fibrillation. The mechanism of action of disopyramide is similar to that of quinidine, and the drug can be used as replacement therapy for quinidine when quinidine side effects are intolerable.

Disopyramide is nearly completely absorbed, and a small fraction undergoes first-pass hepatic metabolism. In the blood, disopyramide binds to plasma proteins. Binding is highly variable among individuals and also depends on the concentration of disopyramide; the higher the concentration, the greater the free fraction. Thus toxicity develops rapidly as the drug concentration increases. The elimination half-life is 4 to 8 hours. Elimination is by renal clearance and hepatic metabolism. Metabolism has a minor role in elimination, but with renal insufficiency, clearance is prolonged, causing accumulation of disopyramide.

Optimal antiarrhythmic effect is accomplished at plasma concentrations of 2.0 to 5.0 μg/mL. The relationship between clinical response and optimal therapeutic concentration is confused by a decrease in protein binding, which occurs as plasma concentration of disopyramide rises.[24] Disopyramide binds variably to serum proteins; binding ranges from 45% to 70% at 2 μg/mL total serum concentration and 30% to 45% at 5 μg/mL.

Disopyramide is metabolized to nordisopyramide (monodealkylated) by the action of CyP 2D6; nordisopyramide has antiarrhythmic activity approximately 25% that of disopyramide. Under normal circumstances, nordisopyramide accumulates to concentrations ranging from 0.2 to 1.0 μg/mL, and the compound does not accumulate out of proportion to disopyramide in situations of reduced hepatic or renal function. Therefore little additional therapeutic information is gained by monitoring nordisopyramide.

The predominant side effects of disopyramide are anticholinergic and include dry mouth, urinary hesitancy, and constipation. These symptoms occur at plasma concentrations exceeding 4.5 μg/mL. Cardiac toxicity is usually associated with blood concentrations greater than 10 μg/mL and is characterized by atrioventricular node blockage, bradycardia, and asystole. Because of the wide degree of variability of protein binding, interindividual differences in the blood concentration at which these symptoms develop are great. Disopyramide is analyzed by HPLC or immunoassay.

Flecainide

Flecainide, proprietary name *Tambocor,* is a sodium channel blocker with cardiac activity like disopyramide. The drug has significant toxicity in patients with myocardial infarction and has therefore fallen out of favor. For those patients who fail to respond to other sodium channel blockers, it might be a drug of last resort.

Flecainide is completely absorbed. It has an elimination half-life of 10 to 17 hours. Elimination occurs by hepatic metabolism (CyP 2D6) and renal clearance. Drugs affecting the CyP 2D6 will interfere with flecainide metabolism. Optimal response occurs when serum levels are in the range of 200 to 1000 ng/mL.[34] HPLC methods for measuring flecanide have been developed.[91]

Lidocaine

Lidocaine, proprietary name *Xylocaine,* is the drug of choice for the initial therapy of PVCs and the prevention of ventricular arrhythmias. Lidocaine is contraindicated when bradycardias and severe atrioventricular node block appear after myocardial infarction. Lidocaine shortens the action potential refractory period in these fibers and does so at concentrations less than those required to exert pharmacological effects at other sites, such as the ventricular myocardium.

Because lidocaine undergoes nearly complete first-pass hepatic metabolism by CyP 3A4 and 2D6 when administered orally, it is administered only as an intravenous or intramuscular injection. Once in the blood, it is 50% bound to protein, mainly to AAG and albumin. Clearance of lidocaine is very rapid. The distribution half-life is ~0.5 hour, and the elimination half-life is 1 to 1.5 hours. Reduced hepatic function impairs clearance and causes prolonged elimination and accumulation of the drug. This is due both to reduced blood flow to the liver (seen in heart failure) and to decreased metabolism of lidocaine. The end effect is lidocaine intoxication if the dose is not adjusted to account for this decreased metabolic rate.

The relationship between optimal blood concentration of lidocaine and its clinical effect is best interpreted in light of the greatest likelihood of therapeutic success, therapeutic failure, or toxicity for selective concentration increments. Blood concentrations less than 1.5 μg/mL are rarely effective. Concentrations ranging from 1.5 to 6.0 μg/mL are usually effective and are rarely associated with any form of central nervous system or cardiovascular toxicity. Concentrations ranging from 4 to 6 μg/mL may be needed for suppressing arrhythmias but may be associated with mild central nervous system depression and slight QRS widening on the electrocardiogram. Concentrations ranging from 6 to 8 μg/mL are acceptable only if alternative therapy is not possible, because these levels have been associated with significant central nervous system depression and atrioventricular node blockage. Concentrations exceeding 8 μg/mL are commonly associated with seizure activity, significant hypotension, and life-threatening decreased cardiac output.

Lidocaine has two metabolites formed by action of Cyp 2D6 and 3A4 that are detected in plasma, monoethylglycinexylidide (MEGX) and glycinexylidide (GX). MEGX and lidocaine have nearly identical toxic equivalency, and the sum total of lidocaine and MEGX concentration averaged 18.7 μg/mL (ranging from 17.9 to 28.0 μg/mL) in patients experiencing lidocaine-induced convulsions. Substitution of MEGX for lidocaine resulted in the same mean concentration for the equivalent convulsive activity.

Because lidocaine is most commonly administered as a constant infusion after a loading dose, the time to collect the specimen is determined by the reason for monitoring. If the blood concentration is intended to document an adequate concentration early in therapy, the specimen should be collected 30 minutes after the loading dose, or 5 to 7 hours after therapy is initiated if no loading dose is given (five half-lives after start of therapy). If a patient shows diminished mental status, QRS widening, or other toxic symptoms, the specimen should be collected as close to the episode as possible and analysis performed immediately, because these symptoms present a potentially life-threatening situation (onset of severe lidocaine intoxication).

The total plasma concentration of lidocaine is a result of clearance of the drug and is modulated by hepatic function. There is little impact on clearance in renal disease. In situations of decreased organ perfusion, clearance is reduced and increased blood concentrations of lidocaine should be expected; reduced dosing is appropriate in these circumstances. The principal binding protein of lidocaine, AAG, has been demonstrated to accumulate after myocardial infarction. The result of accumulation of this protein is reduction of free lidocaine, which reduces the pharmacological effect of the drug. Lidocaine is usually analyzed by immunoassay, and MEGX and GX by HPLC.

Mexiletine

Mexiletine, proprietary name *Mexitil,* is used for control of ventricular dysrhythmias. It undergoes hepatic metabolism by CyP 2D6. The therapeutic concentration varies from 0.7 to 2.0 μg/mL. The drug exhibits a high degree of oral bioavailability, is approximately 60% protein bound, and is predominantly cleared by the kidneys. Mexiletine has a large volume of distribution (5 L/kg), indicating that it is highly tissue bound. Myocardial infarction and uremia reduce renal clearance, resulting in an increase in half-life. Mexiletine toxicity occurs at concentrations greater than 2 μg/mL and is characterized by tremor, dizziness, ataxia, dysarthria, diplopia, nystagmus, confusion, and hypotension.

Procainamide

Procainamide, proprietary name *Pronestyl,* is used for therapy of PVCs, ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia. Its mechanism of action is similar to that of quinidine in that it increases the threshold membrane potential by blocking potassium outflow, reducing excitability and contraction velocity in Purkinje's fibers and ventricular muscle.

Absorption of procainamide is rapid and complete. Peak plasma concentrations after oral administration are reached within 0.75 to 1.5 hours if the drug is given in capsule form or within 1 to 3 hours if given in tablet form. Once absorbed, procainamide is about 20% bound to plasma proteins. Excretion of procainamide depends on hepatic metabolism by *N*-acetyltransferase (NAT1) and renal clearance; therefore alteration in either organ function leads to accumulation of procainamide and its metabolites. The half-life is 3 to 4 hours in healthy adults.

The concentration at which procainamide blocks PVCs and inhibits ventricular tachycardia ranges from 4 to 12 μg/mL, although patients are able tolerate concentrations higher than this for short periods of time. Studies by Meyerburg[82] suggest that patients experiencing chronic PVCs can tolerate blood concentrations as high as 16 μg/mL to reduce PVCs to a reasonable number. Minimum plasma concentrations of 8 μg/mL were required for protection against sustained ventricular tachycardia.

The issue of the ideal therapeutic concentration for procainamide is complicated by one of its metabolites, *N*-acetylprocainamide (NAPA), having antiarrhythmic activity similar to procainamide. This compound has been shown to accumulate in patients with impaired renal function and fast acetylators.[32] The optimal therapeutic concentration of NAPA is not well defined. The drug is used in Europe, where the maximum tolerable concentration of NAPA in the absence of procainamide is 30 μg/mL. Coanalysis of NAPA is necessary to provide a complete assessment of therapy or define metabolic status. Fast acetylators have concentrations of NAPA equal to or exceeding those of procainamide in a specimen collected 3 hours after administration, whereas slow acetylators have procainamide present at greater than twice the NAPA concentration in a specimen collected during the same time interval. Because the effects of procainamide and NAPA are cumulative, peak plasma concentrations of procainamide should be limited to 8 to 12 μg/mL, and peak concentrations of procainamide plus NAPA should not exceed 30 μg/mL. Interpretation of results requires knowledge of a patient's cardiac status. Given concentrations may be intolerable in some patients, whereas others may require higher levels for control of PVCs.

Symptoms of intoxication include (1) bradycardia, (2) prolongation of the QRS interval, (3) atrioventricular block, and (4) induced arrhythmias. These symptoms occur at blood concentrations of procainamide and NAPA exceeding 30 μg/mL. Hypotension sometimes encountered in procainamide therapy is not related to excessive plasma concentration. The development of systemic lupus erythematosus associated with procainamide therapy is not related to plasma concentration but is associated with the acetylator status of the patient; slow acetylators predominate in the group in whom the syndrome develops.

Propafenone

Propafenone, proprietary name *Rythmol,* is an antiarrhythmic drug that has α-adrenergic receptor blocking properties and minor calcium antagonistic activity. It undergoes extensive first-pass metabolism by CyP 2D6 with a half-life of approximately 6 hours. Its clinical efficacy is maintained through formation of metabolites (primarily 5-hydroxypropafenone) that are more pharmacologically active than the parent drug and have longer plasma half-lives (11 to 24 hours). It is occasionally useful to measure the serum con-

centration of propafenone to document patients' compliance. Normal response to the drug occurs when the serum concentration is in the range of 0.2 to 1.0 μg/mL.[51] Toxicity related to propafenone occurs when the blood concentration exceeds 2 μg/mL and is expressed as gastrointestinal upset, central nervous system irritability, and skin reactions.

Propranolol

Propranolol is used in the treatment of arrhythmias of atrial and ventricular origin, angina pectoris, myocardial infarction, and hypertension. It is a nonselective β-blocker with action on cardiac receptors (β_1) and on vascular and bronchial smooth muscle receptors (β_2). Propranolol's principal effect is to reduce the heart rate, thus relieving angina, and to slow conduction at the atrioventricular node, reducing the ventricular rate in patients with atrial fibrillation. It is included here as representative of other β-blockers, such as acebutalol, prindolol, esmolol, flestolol, metoprolol, nadolol, and sotalol, which are like propranolol.

Although propranolol is well absorbed, it undergoes such a high degree of first-pass hepatic metabolism that its final bioavailability is low (20% to 40%), widely variable between individuals, and dose dependent (the higher the dose, the greater the bioavailability). In the plasma, propranolol is highly protein bound (95%) to albumin and AAG. Elimination half-life is 3 to 4 hours. Elimination is predominantly by CyP 1A2 and 2D6 metabolism; therefore, reduced hepatic function or reduced blood flow to the liver causes accumulation of propranolol.

There is a close relationship between slowing of the heart rate and blood concentration.[107] In specimens collected 2 hours after dosing for 2 days with 40 mg of drug four times daily, complete β-adrenergic blockade (equated with suppression of the adrenergic component of exercise-induced tachycardia) correlated with a blood concentration of 100 ng/mL. Blood concentrations in specimens collected 8 hours after the dose, associated with approximately 60% β-adrenergic blockage, ranged from 10 to 40 ng/mL. The same study also documented a close correlation between the blood concentration and the degree of heart rate slowing, suggesting that observation of the heart rate serves as an adequate means to monitor the therapeutic efficacy, precluding blood measurements in most patients. There is virtually no relationship between plasma concentration of propranolol and the hypotensive effect of the drug.

Propranolol and other β-blockers have been analyzed by HPLC using the native fluorescence of the molecule for detection.

Quinidine

Quinidine, available as either quinidine sulfate or quinidine gluconate, is used in the treatment of atrial premature contraction, paroxysmal supraventricular tachycardia, supraventricular tachyarrhythmia, PVCs, and ventricular tachycardia and in prophylactic treatment after myocardial infarction. It is also used with care in the treatment of atrial fibrillation and atrial flutter, although this treatment is commonly accompanied by the administration of either digoxin or a β-blocker (propranolol) to provide atrioventricular node blockade. These pharmacological responses appear to be based on a mechanism of action involving blockade of cholinergic neurotransmission, which results in depression or abolition of ectopic impulse generation, an increase in the duration of action potential of sinoatrial node cells, and most important, prolongation of the effective refractory period of atrial, ventricular, and Purkinje's fibers.

Absorption of quinidine is complete and rapid. Peak serum concentrations are reached in 1.5 to 2 hours after oral intake, unless the slow-release preparation (quinidine gluconate) is used. Peak plasma concentrations are attained 4 to 5 hours after quinidine gluconate administration, and the trough concentration occurs 1 to 2 hours after the next administration. Once absorbed, quinidine is 80% protein bound. Metabolism of quinidine is by CyP 3A4. Clearance of quinidine depends on adequate hepatic and renal function. Reduction of either of these two functions results in accumulation of the drug. Renal clearance is a function of urine pH. If the urine is alkaline or if a patient has renal tubular acidosis, clearance is reduced.

A strong correlation has been shown to exist between blood concentration of quinidine and optimal pharmacological response.[88] The optimal therapeutic concentration for quinidine is 2 to 5 μg/mL. Quinidine toxicity is usually observed at concentrations exceeding 8 μg/mL and is characterized by symptoms of cinchonism, tinnitus, lightheadedness, giddiness, and cardiovascular toxicity, including PVCs and atrioventricular node block. The predominant toxic effect is gastrointestinal distress, including nausea, vomiting, anorexia, and abdominal discomfort. Hypersensitivity reactions associated with quinidine are not related to blood concentration.

Clearance of quinidine depends on CyP 3A4. Induction of this system by drugs such as carbamazepine, phenytoin, and St. John's Wort leads to enhanced clearance of quinidine. Diminished organ perfusion, CyP 3A4 inhibition by grapefruit juice or erythromycin, or co-administration with protease inhibitors results in decreased clearance. Quinidine itself has been reported to dilate peripheral blood vessels, resulting in mild to moderate hypotension and reduced clearance over the short term. Quinidine affects the rate of clearance of digoxin. Quinidine is analyzed by either HPLC or immunoassay. Fluorescence techniques should be considered obsolete.

Tocainide

Tocainide, proprietary name *Tonocard,* has electrophysiological properties similar to lidocaine. It is useful in the management of ventricular arrhythmias typified by a prolonged QT interval. Tocainide has the advantage over lidocaine in that it can be taken orally, and it has a relatively long half-life (13 to 16 hours). Optimal response to tocainide

TABLE 33-3 Pharmacokinetic Parameters of Bronchodilator Drugs

Drug	Minimum Effective Concentration (MEC) (μg/mL)	Minimum Toxic Concentration (MTC) (μg/mL)	Average Half-Life (hr)	Average Volume of Distribution (L/kg)	Average Oral Bioavailability (%)	Average Protein Binding (%)	Important Metabolizing Enzymes
Caffeine	8	14	5 30 (neonates)	0.6	100	35	CyP 1A2
Theophylline	8	20	7-10 (adults) 3-5 (children)	0.5	95	55	CyP 1A2

occurs when the blood concentration is in the range of 6 to 15 μg/mL.[77] At therapeutic concentrations, tocainide is 10% protein bound, does not undergo significant first-pass metabolism, but is metabolized by CyP 2D6. It has a volume of distribution of 3 L/kg, but undergoes significant hepatic metabolism and renal clearance. Toxicity associated with tocainide occurs at concentrations in excess of 15 μg/mL and is characterized by gastrointestinal disturbance, central nervous system irritability culminating in convulsions, and cardiopulmonary depression. HPLC is the method most commonly used for tocainide quantification.

Congestive heart failure and uremia reduce renal clearance and the volume of distribution and increase the clearance half-life. Tocainide is not highly protein bound, so it does not exhibit the protein-binding phenomenon described for lidocaine after myocardial infarction. Clinically, the dose should be reduced proportionally to glomerular filtration to maintain therapeutic levels.

Verapamil

Verapamil, proprietary name *Calan,* is a calcium channel blocker that is effective in the treatment of various cardiovascular disorders, including angina (classical and variant), arrhythmias (paroxysmal supraventricular tachycardia), atrial flutter, atrial fibrillation, hypertrophic cardiomyopathy (idiopathic hypertrophic subaortic stenosis), hypertension, congestive heart failure, and Raynaud's phenomenon, along with the preservation of ischemic myocardium and the treatment of migraine headaches.

There is a good correlation between cardiac responsiveness and blood concentration.[50] The effective blood concentration of verapamil ranges from 50 to 250 ng/mL. CyP 3A4 and 1A2 metabolize verapamil; it is a potent inhibitor of CyP 3A4. Sinus bradycardia and heart block occurring at blood concentrations exceeding 250 ng/mL characterized toxic symptoms. All subjects studied showed atrioventricular block at concentrations exceeding 450 ng/mL. HPLC is the method used for quantification of this drug.

Other Cardioactive Drugs

Diuretics and angiotensin-converting enzyme inhibitors are being used to treat cardiac problems.[51] In general, pharmacological effects of these new diuretics and angiotensin-converting enzyme inhibitors are monitored by physiological function rather than by measuring blood levels.

BRONCHODILATORS

Drugs used as bronchodilators include the β-adrenergic agonists, caffeine, and theophylline. Pharmacokinetic details of some bronchodilators are summarized in Table 33-3.

β-Adrenergic Agonists

β-Adrenergic agonists, such as albuterol, bitolterol, isoproterenol, metaproterenol, pirbuterol, and terbutaline in the inhaled form, have become the treatment of choice for a short-acting approach to relief of asthma. These drugs are very effective at providing rapid bronchodilation without significant cardiac or systemic effects. Because they are administered in the vapor form, have short time of action, and produce little toxicity, measurement of blood levels offers little clinical benefit; patient response provides a convenient form of monitoring therapy.

Caffeine

A minor metabolite of theophylline in adults, caffeine has been shown to accumulate to significant concentrations in neonates. Caffeine itself is an effective inhibitor of apnea, which may explain the lower therapeutic concentration required for control of neonatal apnea. Therapy with caffeine alone has also been demonstrated as effective in the treatment of neonatal apnea; it is gaining popularity because of caffeine's long half-life in neonates (>30 hours). Caffeine is metabolized by CyP 1A2; this enzyme is not active in neonates. The optimal therapeutic concentration of caffeine in this situation ranges from 8 to 14 μg/mL. Caffeine is measured by HPLC or immunoassay.

Theophylline

Theophylline, available under many proprietary names, relaxes bronchial smooth muscles to relieve or prevent asthma. The therapeutic effect of theophylline is likely due to antagonism of adenosine receptors in smooth muscle, whereas the toxic effects are due to inhibition of cyclic nucleotide phosphodiesterase. With increased use of β-adrenergic agonists, and because of the considerable toxicity associated with it, theophylline is now considered

TABLE 33-4 Pharmacokinetic Parameters of Commonly Monitored Antibiotic Drugs

Drug	Minimum Effective Concentration (MEC)* (μg/mL)	Minimum Toxic Concentration (MTC) (μg/mL)	Average Half-Life (hr)	Average Volume of Distribution (L/kg)	Average Oral Bioavailability (%)	Average Protein Binding (%)
Amikacin	25	35	2.5	0.3		5
Ciprofloxacin	<0.2	4	4	2	100	40
Chloramphenicol	10	25	3	0.9	75-90	53

Kanamycin	25	35	2.1	0.25		0
Sulfonamides, all	75	125	6-10	0.2	100	70-90
Tobramycin	<5	8	2	0.3		<10
Vancomycin	20	40	6	0.5		<10

*Organism sensitivity studies (minimum inhibitory concentration; see text) define the minimum effective concentration.

an alternative therapy used only in treatment of persistent asthma when albuterol or its analogs are not effective.[132]

Theophylline is readily absorbed after oral, rectal, or parenteral administration. If the drug is taken orally without food, the blood concentration peaks within 2 hours. If it is administered with food or as the slow-release formula, peak concentrations occur 3 to 5 hours after the dose. Once absorbed, it is 50% protein bound. Theophylline is metabolized by CyP 1A2, which is highly active in children and in adults who smoke. In these people, the half-life ranges from 3 to 4 hours. Nonsmoking adults in good health have an elimination half-life averaging 9 hours. The half-life in neonates and in adults with congestive heart failure can be prolonged to 20 to 30 hours, depending on the degree of liver immaturity or loss of liver function. Co-administration of cimetidine, ciprofloxacin, and ticlopidine will reduce the clearance of theophylline.

The relationship between serum concentration and prevention of symptoms of chronic asthma has been documented.[52] There is a proportional relationship between forced expiratory volume and theophylline concentration, with the optimum therapeutic effect occurring at concentrations ranging from 8 to 20 μg/mL. Suppression of exercise-induced bronchospasm in asthmatic patients occurs at concentrations exceeding 10 μg/mL and is optimal at 15 μg/mL. Neonatal apnea treated with theophylline responds to slightly lower concentrations, ranging from 5 to 10 μg/mL. Relaxation of bronchial smooth muscle is directly proportional to blood concentration and continues at concentrations greater than 20 μg/mL. When the blood level exceeds 20 μg/mL, the secondary side effects become significant.

Theophylline clearance is a function of a metabolic process that is dose dependent. At serum concentrations greater than 20 μg/mL, small dose increases lead to disproportionately large increases in serum concentration and intoxication. Symptoms of theophylline toxicity include nausea, vomiting, headache, diarrhea, irritability, and insomnia. Transient central nervous system stimulation occurring at initial administration is not directly related to blood concentration. This effect diminishes with chronic use. Serious toxicity characterized by cardiac arrhythmias and seizures is usually associated with serum concentrations in excess of 30 μg/mL. Once seizure activity begins, the final prognosis is very poor. Morbidity is reported in nearly all patients, and mortality can be as high as 50%.[157]

Immunoassay is the standard method for the determination of theophylline. Theophylline, caffeine, and dyphylline have been simultaneously quantified by HPLC.

Antibiotics

Antibiotics that require TDM include aminoglycosides, chloramphenicol, sulfonamides, vancomycin, trimethoprim, β-lactams, and tetracyclines. Pharmacokinetic details of these antibiotics are summarized in Table 33-4. Aminoglycosides and vancomycin are quantified by immunoassay. Other antibiotics have been measured by HPLC.

Aminoglycosides

Aminoglycosides are polycationic agents that kill aerobic gram-negative bacteria. They act by binding to the 30S ribosomal subunit of bacterial mRNA, thereby inhibiting protein synthesis. They are inactive under anaerobic conditions because an oxygen-dependent active transport mechanism is involved in the transfer of aminoglycosides across the bacterial cell wall. The aminoglycoside class of drugs includes amikacin, gentamicin, kanamycin, neomycin, netilmicin, sisomicin, streptomycin, and tobramycin.

The aminoglycosides are a very polar group of compounds and are thus poorly absorbed from the intestinal tract. They are routinely administered intravenously or intramuscularly to achieve a high degree of bioavailability.

TABLE 33-5 Minimal Inhibitory Concentrations of Antibiotics*

Antibiotic	Susceptible (μg/mL)	Intermediate (μg/mL)	Resistant (μg/mL)
Amikacin	<16	32	>64

*Note: Does not apply to pulse dosing.

When administered directly into the blood, they rapidly distribute to the extracellular fluid but do not cross cell membranes or bind to plasma proteins; this behavior is consistent with their unusually low volume of distribution. Most tissues and nonrenal or hepatic secretions contain very small concentrations of aminoglycosides, the exceptions being the renal cortex, where the drug is concentrated, and bile because of active hepatic secretion. The drugs are mainly excreted by glomerular filtration. Elimination half-lives are short, ranging from 2 to 3 hours. Because clearance is highly dependent on renal function, any impairment of glomerular filtration causes accumulation of these drugs.

Therapy with antimicrobial agents differs from the approach used for most other drugs discussed in this chapter. With them, the goal is to achieve a concentration in plasma such that the bacteria are killed but the host remains undamaged. Because the organisms treated are variable and can become resistant to certain drugs, treatment with specific aminoglycoside agents should always be directed by susceptibility testing. Effective minimal inhibitory concentrations of these drugs are listed in Table 33-5.

A limit to the blood concentration of aminoglycosides has been recommended, although considerable variability is reported regarding the relationship of blood concentration to later onset of toxicity.[78] Renal tubular necrosis and degeneration of the auditory nerve are the side effects most frequently experienced after exposure to high concentrations of aminoglycosides. Both peak and trough specimens are required to monitor toxicity. Table 33-6 identifies target maximum peak and trough serum concentrations; in this mode of monitoring, the intent of therapy should be to dose the patient in such a manner that the peak concentration does not exceed these limits. In a large surgical patient survey in which dosing was carried out under controlled conditions, limited nephrotoxicity was experienced when the peak serum concentration of gentamicin was maintained below 8 μg/mL.[155]

Dose corrections must be made in patients with compromised renal function because these patients have prolonged half-life and slower elimination. Guidelines have been prepared (Table 33-7) that allow application of creatinine clearance to estimate adequate initial dose.[121] This

TABLE 33-7 Useful Guidelines for Gentamicin Dose Calculated from Lean Body Weight and Creatinine Clearance

1. Select loading dose in mg/kg (lean weight) to provide peak serum level desired. Approximate peak levels from commonly used loading doses are indicated below.

Loading Dose	Expected Peak Serum Concentration Based on 30-min IV Infusion, (μg/mL)
2.0 mg/kg	6-8
1.75 mg/kg*	5-7
1.5 mg/kg	4-6
1.25 mg/kg	3-5
1.0 mg/kg	2-4

2. Select maintenance dose (as percentage of chosen loading dose) to continue peak serum levels indicated above according to patient's creatinine clearance (*Ccr*) and desired dosing interval.

	Percentage of Loading Dose Required for Dosage Interval Selected†		
Ccr	8 hr	12 hr	24 hr
90	90	—	—
80	88	—	—
70	84	—	—
60	79	91	—
50	74	87	—
40	66	80	—
30	57	72	92
25	51	66	88
20	45	59	83
15	37	50	75
10	29	40	64
7	24	33	55
5	20	28	48
2	1	20	35
0	9	13	25

*Recommended for most moderate to severe systemic infections.
†Shaded areas indicate suggested dosage intervals.

should then be followed up by quantification of the blood concentration and dose adjustment following the method outlined by Gilbert.[44]

Toxicity associated with aminoglycosides manifests as delayed-onset vestibular and cochlear sensory cell destruction and acute renal tubular necrosis. The degree and severity of cell damage are variable among the various drugs, but they all cause cell damage if the concentrations exceed the limits listed in Table 33-4. Unfortunately, the guidelines identified in Table 33-6 do not guarantee the avoidance of toxicity; a small number of patients experience toxic effects regardless of the concentration. Fortunately, most patients reverse the toxic effects without direct intervention if the toxicity is associated with reasonable blood concentrations (see Table 33-7). Irreparable loss of vestibular, cochlear, or renal function usually correlates with administration of one of the aminoglycosides at elevated blood concentrations for periods longer than 2 weeks.

Aminoglycosides display peak concentration–dependent killing of microorganisms. Clinically, the therapeutic goal is to achieve peak concentrations 10 times the minimum inhibitory concentration (MIC) of the organism. Once per day dosing of two or more times the usual 48-hour dose (known as pulse dosing) may minimize the development of adaptive resistance, and nephrotoxicity may be decreased or delayed. Target peak concentrations are typically more than twice the target concentrations for the usual 48-hour dosing regimen (see Table 33-6). Reports of reactions similar to endotoxemia (chills, rigors, fever, hypotension, tachycardia, and respiratory distress) have been associated with once daily therapy. Most studies with pulse dosing of aminoglycosides have been performed in patients with low failure rates in urinary tract infections or abdominal and/or pelvic infections. These patient groups may be good candidates for pulse dosing. Patients who are critically ill or who are suspected to have considerably higher than normal volumes of

distribution may not achieve desired peak concentrations. Quantification of the drug concentration at 2 hours after the end of a 1 hour infusion and an 8 to 12 hour concentration after the first dose can be used to calculate individual patient pharmacokinetic parameters (e.g., extrapolated peak and trough, half-life, etc.) and the dose optimized. See Case Study No. 3 on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/ for an example of how to perform these calculations.

Heparin has been implicated as a deactivator of gentamicin by formation of an inactive complex. This complex, although biologically inactive, retains some structural resemblance to the initial aminoglycoside and cross-reacts with antibodies to the specific aminoglycoside. Heparin concentrations encountered in therapeutic antithrombotic therapy are less than 3 units/mL, making an in vivo complication unlikely. However, specimen collection tubes containing heparin (1000 units/mL) may lead to complex formation, a phenomenon that could interfere with some immunoassay procedures. In practice, aminoglycoside antibiotics are measured by immunoassay.

Chloramphenicol

Chloramphenicol, proprietary name *Chloromycetin* and others, is used as a bactericidal agent. It acts by binding to the 50S ribosomal subunit of bacteria mRNA, and inhibits protein synthesis in prokaryotic organisms. Use of this drug depends on its relative toxicity against the microorganism versus the host. The drug is used against gram-negative bacteria such as *Haemophilus influenzae, Neisseria meningitidis, Neisseria gonorrhoeae, Salmonella typhi,* all *Brucella* species, *Bordetella pertussis, Vibrio cholerae,* and *Shigella.* These organisms all are susceptible to a serum concentration of 6 μg/mL. Organisms that are susceptible to a concentration of 12 μg/mL are *Escherichia coli, Klebsiella pneumoniae, Pseudomonas pseudomallei, Chlamydia,* and *Mycoplasma.*

Chloramphenicol is rapidly absorbed in the gastrointestinal tract. Peak serum concentrations occur 1 to 2 hours after the oral dose. In plasma, chloramphenicol is approximately 50% protein bound and is cleared with a half-life of 2 to 3 hours. Peak serum concentrations after administration of chloramphenicol palmitate or succinate occur 4 to 6 hours after the dose. Chloramphenicol distributes to all tissues, and it concentrates in the cerebrospinal fluid. The drug is actively metabolized by the liver by NAT1 and UGT. Thus chloramphenicol accumulates in cases of hepatic disease. Renal disease does not dramatically reduce clearance.

Toxicity associated with chloramphenicol therapy includes blood dyscrasias and cardiovascular collapse; both show a modest relationship to blood concentration. Other blood concentration–related toxicities include anemia, characterized by maturation arrest in the marrow; cytoplasmic vacuolation of early erythroid and myeloid cells; reticulocytopenia; and increases in both serum iron and serum iron–binding capacity. These symptoms all are associated with serum concentrations in excess of 25 μg/mL. Development of aplastic anemia is not related to dose or blood concentration. Cardiovascular collapse, which occurs primarily in newborns, has been related to a total serum chloramphenicol concentration in excess of 50 μg/mL. An oral dose of 50 mg/kg/d results in an optimal peak serum concentration of 10 to 25 μg/mL in a healthy adult.

Procedures for the determination of chloramphenicol concentrations in blood serum include HPLC and immunoassay. Methods for chloramphenicol determination must be able to differentiate between the prodrug forms, chloramphenicol palmitate or succinate, and their active metabolite, chloramphenicol. (An HPLC method for measuring chloramphenicol is included on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.)

Fluoroquinolones

Fluoroquinolones, characterized by ciprofloxacin, gatifloxacin, levofloxacin, and moxifloxacin (Figure 33-12), have antibiotic activity against gram-positive (*Streptococcus pneumoniae* and *pyogenes, Staphylococcus aureus,* and *Enterococcus faecalis*); gram-negative (*Escherichia coli, Haemophilus influenzae, Moraxella catarrhalis, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa*); and atypical pathogens (*Chlamydia pneumoniae, Mycoplasma pneumoniae,* and *Legionella pneumophila*). They are administered orally at doses varying from 200 to 800 mg twice per day. Maximum serum concentrations are attained 1 to 2 hours after oral dosing. Peak serum concentrations after a standard dose average 1 to 4 μg/mL. Trough concentrations at 12 hours after dose are >0.2 μg/mL.

Fluoroquinolones distribute into most tissues with an apparent volume of distribution of 1.5 to 2 L/kg. They have serum half-lives of ~4 hours and renal clearance of ~6 mL/min/kg; clearance is reduced in renal failure. They are ~40% protein bound and metabolized by hepatic conjugation (UGT); they undergo little phase I metabolism. Symptoms of toxicity include restlessness, diarrhea, and gastrointestinal upset. Skin rash may be a sign of sensitivity to fluoroquinolones.

Because fluoroquinolones have a wide therapeutic index and dose-dependent toxicity, routine drug monitoring is not indicated. Monitoring fluoroquinolone concentration is indicated in renal failure, which will cause fluoroquinolones to accumulate. Optimal response occurs when serum concentration exceeds 1.5 μg/mL. Activity is maintained as long as the trough concentration is >0.2 μg/mL. Co-administration with antacids, ferrous sulfate, food, or sucralfate reduces absorption by 30% to 60%. Co-administration with morphine reduces absorption by >50%.

Sulfonamides

Sulfonamides act by competitively antagonizing bacterial use of *p*-aminobenzoic acid, which is important in the synthesis of folic acid. Therefore, organisms dependent on self-

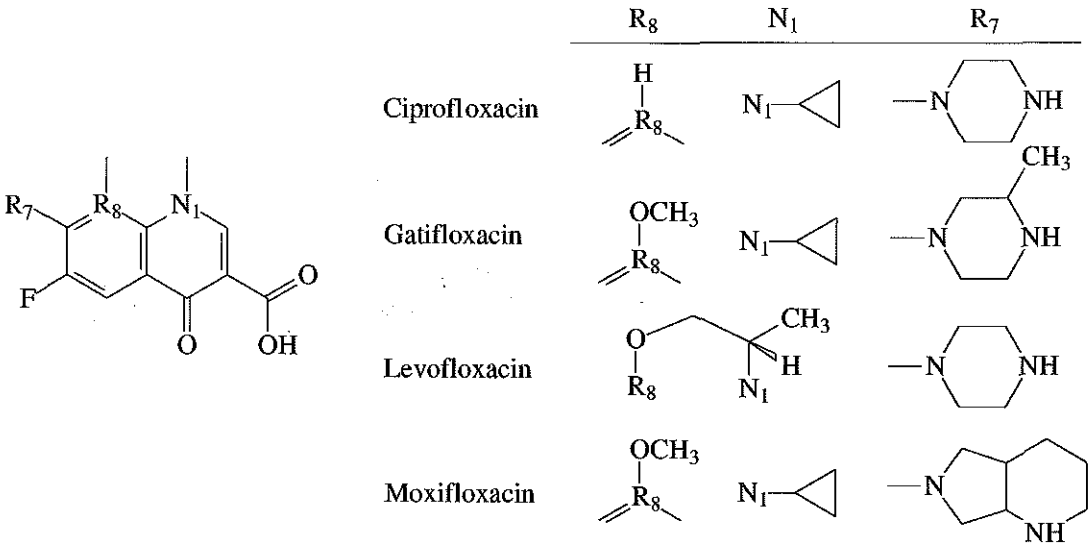

Figure 33-12 Chemical structures of fluoroquinolones.

synthesized folic acid for growth are susceptible to sulfonamides. Sulfonamides are used against common urinary tract pathogens such as *E. coli, Klebsiella, Enterobacter, Proteus mirabilis,* and indole-positive *Proteus* species. They are not used for infections caused by *Pseudomonas aeruginosa.* The sulfonamides are active against *H. influenzae, Streptococcus pneumoniae, Shigella flexneri,* and *Shigella sonnei* isolated from the middle ear or bronchial secretions.

The sulfonamides are nearly completely absorbed from the gastrointestinal tract. Once absorbed they are bound to protein (60% to 90%), mainly to albumin, and are distributed to all tissue. Metabolism is by *N*-acetylation, with the products having no antimicrobial activity.

Blood dyscrasias associated with sulfonamide use are not related to dose or blood concentration of the drug. The predominant toxicity associated with sulfonamide use is the formation and deposition of crystalline aggregates in the kidney, ureter, and bladder. The safe and effective peak concentration of these drugs in serum (75 to 125 μg/mL) is well separated from the serum concentration at which crystallization in the urinary tract occurs. Serum concentrations in excess of 300 μg/mL maintained for prolonged periods of time have been associated with such crystal formation. The method of choice for quantification of sulfonamides is HPLC.[43]

Vancomycin

Vancomycin is a glycopeptide that has bactericidal action against gram-positive bacteria and some gram-negative cocci. Vancomycin is used because of its activity against methicillin-resistant staphylococci and corynebacteria. It has thus become popular for treatment of endocarditis and sepsis caused by these organisms.

Although the drug is poorly absorbed when given orally, a 1-g dose given intravenously every 12 hours accomplishes a peak blood concentration of 20 to 40 μg/mL and a trough concentration of 5 to 10 μg/mL. It has an average elimination half-life of 5 to 6 hours. Blood concentration–related toxicity involves the auditory nerve. Concentrations less than 30 μg/mL are rarely associated with this development. Toxicities not related to dose or blood concentration are rare and include fever, phlebitis, and pain at the infusion site. In patients with impaired renal function, the serum concentration may increase to toxic levels because of reduced clearance. Immunoassay is the standard technique for monitoring concentration.

Miscellaneous Antibiotic Drugs

Trimethoprim is administered as a combination drug with sulfamethoxazole. The drug is excreted in proportion to sulfamethoxazole; it is not toxic and therefore is not commonly monitored. Sulfa determination may be used to establish compliance.

Adverse reactions to β-*lactams* (penicillins and cephalosporins) are not related to dose or blood concentrations. They are commonly administered in doses 10 to 100 times greater than necessary to inhibit organism growth, and appropriate dosing may be guided by susceptibility testing. Patient compliance and evaluation of patients with renal impairment are the most likely reasons to monitor the blood concentration.

Tetracyclines are broad-spectrum antibiotics. They are not highly toxic, and therefore, like the β-lactams, the need to monitor their serum concentrations is limited to monitoring patient compliance and adjusting dose in patients with impaired renal function.

Table 33-8 lists pharmacokinetic data for other antibiotics.[78]

Antiretrovirals

Successful treatment of human immunodeficiency virus (HIV-1) infection has been achieved through successful implementation of highly active antiretroviral therapy, frequently referred to as HAART. This involves simultaneous administration of both nucleoside and nonnucleoside reverse transcriptase inhibitors and one or more protease inhibitors. The common nucleoside reverse transcriptase inhibitors are the thymidine analogs didanosine (ddI), lamivudine (3TC), and zalcitabine (ddC); and the non-thymidine analogs abacavir (Ziazen), stavudine (d4T), and zidovudine (AZT). The nonnucleoside reverse transcriptase inhibitors include delavirdine, efavirenz, and nevirapine. The protease inhibitors include indinavir, nelfinavir, ritonavir, and saquinavir. Response to therapy is monitored by quantification of HIV-RNA copies (viral load) and CD-4+ T-lymphocyte count. Successful therapy is indicated when viral load is reduced to <50 copies/mL and CD-4+ count >500 per mL.

Because treatment success is highly dependent upon adherence to therapy and development of viral resistance is potentiated by noncompliance, patients must be continuously reminded to adhere to their dosing schedules at all times. Drug monitoring is used as a tool to assess patient compliance. Aggressive counseling would be indicated if the blood concentration of the prescribed drugs becomes nondetectable. Pharmacokinetic parameters of antiretrovirals are outlined in Table 33-9. A method to quantify antiretrovirals, with recommended reference intervals, has been published.[92] Tandem MS is becoming the method of choice for monitoring HAART because it is less prone to interference by the common multidrug combinations.[145]

Antipsychotic Drugs

Drugs used in psychiatric care that are commonly monitored include antidepressants, some neuroleptics, and lithium. Pharmacological parameters of these antipsychotic drugs are shown in Table 33-10.

Antidepressants

Antidepressants are used to treat endogenous depression characterized by depressed mood, feelings of guilt, appetite suppression, insomnia, weight change, diminished ability to concentrate, loss of interest or pleasure in usual activities, and decreased sexual drive. In more severe cases, depersonalized behavior, paranoid behavior, obsessive-compulsive behavior, and suicidal tendencies are obvious. The antidepressants include (1) amino ketones (bupropion [*Wellbutrin*]), cyclohexanols (venlafaxine [*Effexor*]), (2) dibenzoxazepines (amoxapine [*Asendin*]), (3) diphenylamines (fluoxetine [*Prozac*]), (4) naphthalenamines (sertraline [*Zoloft*]), (5) tetracyclics (maprotiline [*Ludiomil*]), (6) triazoles (paroxetine [*Paxil*], and trazodone [*Desyrel*]), and (7) tricyclics (amitriptyline [*Elavil*], clomipramine [*Anafranil*], desipramine [*Norpramine*], doxepin [*Sinequan*], imipramine [*Tofranil*], nortriptyline [*Pamelor*], protriptyline [*Vivactil*], and trimipramine [*Surmontil*]).

Endogenous depression implies that there is no apparent organic or societal cause of these behavior changes. Treatment of depression with the tricyclic or tetracyclic depressants results in pharmacological activity through inhibition of the reuptake of catecholamines in the central nervous system. The end result is a positive effect on mood. The optimal therapeutic concentrations and important pharma-

*NA, Not applicable.

cokinetic parameters of antidepressants are listed in Table 33-10.

Tricyclic Antidepressants

Tricyclic antidepressants are nearly completely absorbed from the gastrointestinal tract but undergo first-pass hepatic metabolism, so their ultimate bioavailability is variable. Because these drugs slow gastrointestinal activity and gastric emptying, their absorption may be delayed. Once absorbed, they are highly protein and tissue bound, resulting in large apparent volumes of distribution. Peak plasma concentrations are reached from 2 to 12 hours after the oral dose. Metabolism is by CyP 2C19, 2D6, and 3A4 *N*-demethylation and aromatic ring hydroxylation, followed by conjugation (UGT). If the drug administered is the tertiary tricyclic amine (amitriptyline, doxepin, and imipramine), metabolism causes accumulation of the respective secondary amine (nortriptyline, nordoxepin, and desipramine). These substances have generally equal pharmacological activity and accumulate to concentrations approximately (but variably) equal to the parent drug. The hydroxylated metabolites have little pharmacological activity. Taking factors such as variable bioavailability, high volume of distribution, variable metabolic activity, and generation of pharmacologically active metabolites into consideration, it is not surprising that patient response to these drugs is widely variable. Determining the serum concentration gives the physician the assurance that a patient has been properly dosed.

Drugs such as cimetidine, chloramphenicol, haloperidol, methylphenidate, and phenothiazines generally inhibit hepatic oxidative enzymes. Inhibition of end-product metabolism of the tertiary tricyclic antidepressants results in a greater accumulation of the secondary amine metabolite (amitriptyline is metabolized to nortriptyline, doxepin to nordoxepin, imipramine to desipramine), because conversion to the aromatic ring hydroxylated metabolites is blocked. Co-administration of perphenazine with a tricyclic antidepressant causes accumulation of the secondary amine to concentrations two to four times normal, with onset of toxicity occurring at the expected blood concentrations.

Tricyclic antidepressants show a good correlation between therapeutic response and serum concentration. A linear relationship between clinical improvement and serum concentration is noted for most of these drugs, the exception being nortriptyline, which has a specific therapeutic window. A serum concentration of nortriptyline below or above the concentration range of 50 to 150 ng/mL correlates with worsening of moods. The other antidepressants do not display this effect; the upper limit of the optimum blood concentration for these other antidepressants is limited by the onset of toxicity. Toxicity is expressed as dry mouth and perspiration, signs that may also occur with depression. Thus it is difficult to differentiate between mild toxicity caused by the drug and the disease that is being treated. More serious toxicity is expressed as atrioventricular node block, characterized by a widening of the electrocardiographic QRS interval. Onset occurs at serum concentrations ranging from 800 to 1200 ng/mL, and the severity of intoxication is related to the serum concentration. The relationship between serum concentration and cardiac toxicity diminishes with time

after intoxication as the drug is absorbed into tissues. Despite this toxicity, the tricyclic antidepressants remain very important drugs in the treatment of depression.

Numerous methods have been published for analysis of tricyclic antidepressants. These drugs present various problems to the clinical laboratory: (1) the therapeutic serum concentration is 10 to 100 times lower than that of other commonly monitored drugs, and thus to be clinically useful, the method must be able to measure serum concentrations <50 ng/mL; (2) these drugs have metabolites that must also be measured; and (3) these drugs are structurally similar to common sleep inducers, antihistamines, and many over-the-counter medications used for appetite suppression, which are potential interferences. Of the many hundreds of methods published, only a few have satisfactorily overcome these obstacles.

Analysis by gas chromatography-mass spectrometry (GC/MS) using selected ion monitoring is the reference method.[9] Methods for trazodone[141] and amoxapine[21] are also available. HPLC has been successfully used for analysis of tricyclic antidepressants, although separation and selectivity are problems with this technique.[80]

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are frequently prescribed medications. Their therapeutic actions are diverse, ranging from efficacy in depression to obsessive-compulsive disorder, panic disorder, bulimia, and other conditions.[131] They include bupropion, fluoxetine, nefazodone, paroxetine, and miscellaneous other drugs.

Bupropion. Bupropion is a weak blocker of serotonin, norepinephrine, and dopamine. Bupropion is rapidly absorbed, reaching peak level within 2 hours of oral administration. It is thought to undergo considerable first-pass metabolism, although studies have not been done to confirm this because the drug is not available in intravenous form. It is estimated that bioavailability ranges from 5% to 20%. Bupropion is metabolized by CyP 3A4, 2B6, and 2D6. Major metabolites include the hydroxylated morphinol-metabolite and the *threo*-amino alcohol metabolite. The half-life of bupropion ranges from 8 to 24 hours. On a typical daily dose (100 to 250 mg), bupropion serum levels correlate with dose and are in the range of 25 to 100 ng/mL. Methods to measure serum concentration have been developed.[134]

Fluoxetine. Fluoxetine (and other nontricyclic antidepressants) acts by inhibiting serotonin uptake in the central nervous system. The drug has fewer antagonistic effects on muscarinic, histaminic, and α-adrenergic receptors than the tricyclic antidepressants, allowing it to be used with fewer side effects. Fluoxetine is metabolized by CyP 3A4, 2D6, and 2C19. Fluoxetine has a very long half-life (48 hours), and its active metabolite, norfluoxetine, is eliminated with a half-life of 180 hours. Optimal response to fluoxetine occurs when the plasma concentration is in the range of 90 to 300 ng/mL.[110] Norfluoxetine is usually present at approximately the same concentration as fluoxetine. The drug undergoes significant hepatic metabolism, and blood levels are affected by liver disease. Compromised renal function has little effect on the excretion rate of fluoxetine.

Nefazodone. Nefazodone is an antidepressant that inhibits neuronal uptake of serotonin and norepinephrine. Nefazodone is a 5-HT_2 antagonist that is rapidly absorbed and has low bioavailability (20%) because it undergoes first-pass metabolism. In March of 2004, the U.S. FDA issued a Public Health Advisory that called attention to reports of both suicidal ideation and suicide attempts in children taking antidepressant drugs such as nefazodone for the treatment of major depressive disorder (MDD). Because of several cases of liver toxicity, nefazodone (Serzone) was taken off the market in June of 2004. An HPLC method with electrochemical detection has been published for the analysis of nefazodone.[39]

Paroxetine. Paroxetine is a selective serotonin reuptake inhibitor with demonstrated clinical utility as an antidepressant. Paroxetine is completely absorbed after oral ingestion and reaches peak steady-state levels of 30 to 70 ng/mL in approximately 5 hours. It undergoes hepatic metabolism by Cyp 2D6, has a half-life of 21 hours, and metabolites are inactive. Steady-state concentrations of paroxetine on a typical dose of 20 mg/day are achieved in 10 days. Clinical response appears to be related to serum concentration[110] and a chromatographic method is available.[48]

Other SSRIs. The antidepressants amoxapine, fluoxetine, sertraline, trazodone, and venlafaxine do not have the same degree of cardiac toxicity that plagues the tricyclic and tetracyclic antidepressants. Treatment with doses slightly greater than normal does not predispose the patient to major toxicity. Therefore monitoring levels of these drugs is not required to avoid toxic side effects. However, if the patient is not responding to the drug as expected, monitoring the level may be useful in demonstrating noncompliance. A variety of methods are available for measuring these antidepressants in body fluids.[80]

Lithium

Lithium, whose proprietary names include *Eskalith, Lithane, Lithonate,* and others, is administered as lithium carbonate and used for treatment of the manic phase of affective disorders, mania, and manic-depressive illness. It is postulated to act by enhancing reuptake of catecholamines, thereby reducing their concentration in the neuronal junction. This produces a sedating effect on the central nervous system. Lithium also modulates the distribution of sodium, calcium, and magnesium in nerve cells, which reduces the rate of glucose metabolism that effects nerve function. The actual mechanism of action of lithium in affecting mania remains theoretical.

Absorption of lithium from the gastrointestinal tract is complete, with peak plasma concentration reached 2 to 4 hours after an oral dose. This cation does not bind to protein. Lithium elimination is biphasic; during the first phase, 30% to 40% of the dose of lithium is cleared, with an

apparent half-life of 24 hours. During the second phase, the remainder of lithium incorporated into the cellular ion pool is cleared, exhibiting a half-life of 48 to 72 hours. Clearance is predominantly a function of the kidneys, where active reabsorption occurs. Reduced renal function causes prolonged clearance times.

The optimal therapeutic response to lithium has not been related to a specific serum concentration. However, toxicity is related to serum concentration and consequently serum lithium concentrations are monitored to ensure patient compliance and to avoid intoxication. It has been recommended that a standardized 12-hour postdose serum lithium concentration be used to assess adequate therapy.[91] The interval of 1.0 to 1.2 mmol/L was identified as the optimal trough therapeutic concentration. Concentrations of 1.2 to 1.5 mmol/L signified a warning range, and a concentration in excess of 1.5 mmol/L *in a specimen drawn 12 hours after the dose* indicates a significant risk of intoxication. Early symptoms of intoxication include apathy, sluggishness, drowsiness, lethargy, speech difficulties, irregular tremors, myoclonic twitchings, muscle weakness, and ataxia. These symptoms, although not life threatening, are uncomfortable for patients and indicate that the onset of life-threatening seizures is imminent.

Lithium excretion parallels that of sodium. It readily passes the glomerular membrane and is reabsorbed in the proximal convoluted tubules. In situations in which patients are vulnerable to dehydration (fever, watery stools, vomiting, loss of appetite, and hot weather), the potential for lithium intoxication is increased. In dehydration, the proximal tubular response to reabsorption of sodium (and lithium) is reduction of clearance. Increased reabsorption of lithium leads to increased blood concentration of lithium. Severe intoxication, characterized by muscle rigidity, hyperactive deep tendon reflexes, and epileptic seizures, is usually associated with lithium concentrations in excess of 2.5 mmol/L.

The concentration of lithium in serum, plasma, urine, or other body fluids has been determined by flame emission photometry, atomic absorption spectrometry, or electrochemically using an ion-selective electrode. Serum analysis, the most useful specimen for lithium monitoring, is most commonly quantified by automated spectrophotometric assay.

Other Antipsychotic Drugs

Psychotic patients are most often treated with clozapine, haloperidol, lithium, olanzapine, or one of the phenothiazines, or a combination of these drugs. Because response to these drugs is unpredictable and patients are difficult to control, monitoring serum concentration may aid in adjusting therapy. Numerous methods to measure the serum concentration of the various neuroleptic agents have been reported.[23]

Quantitative procedures for haloperidol and phenothiazines suffer from a major drawback: they are too specific. The major problem encountered with monitoring these drugs is the number of active metabolites of each. Numerous metabolites have been reported for the common phenothiazines, most of which have some pharmacological activity.[19] Thus therapeutic monitoring of these drugs requires co-analysis of numerous metabolites, an option that is analytically problematic, and reference materials for most of the metabolites are not available.

Clozapine

Clozapine, proprietary name *Clozaril,* is an effective antipsychotic drug that inhibits dopamine binding at the D-1 and D-2 receptors, and more actively binds at limbic binding sites than at striatal sites. Clozapine undergoes hepatic metabolism by CyP 3A4 and 1A2 to yield numerous, inactive metabolites; the serum half-life of clozapine is 4 to 12 hours. On a typical daily dose (100 mg bid), clozapine is 97% bound to plasma proteins. Patients respond to the drug when trough serum concentrations of clozapine are in the range of 100 to 600 ng/mL, and methods of analysis have been described.[69]

Clozapine is likely to produce agranulocytosis in approximately 1% of patients who receive the drug. This toxicity is an exposure-related event that occurs regardless of blood level. For this reason, use of clozapine is limited to schizophrenic patients who do not respond to conventional treatment. Biweekly monitoring of white cell count is required in all patients prescribed this drug.

Olanzapine

Olanzapine, a thienobenzodiazepine with proprietary name *Zyprexa,* is a serotonin and dopamine antagonist with antimuscarinic activity. It also blocks histamine receptors. It is completely absorbed to reach peak concentrations in the range of 1000 ng/mL in 6 hours. Olanzapine has a half-life averaging 35 hours. It is 93% protein bound. Olanzapine is cleared by CyP 1A2 metabolism to inactive desalkyl amine and by UGT to *N*-glucuronide metabolites. An HPLC method with electrochemical detection for measuring olanzapine has been published.[16]

Quetiapine

Quetiapine, a dibenzothiazepine with proprietary name *Seroquel,* is an antipsychotic drug similar to clozapine; it inhibits dopamine binding at the D-1 and D-2 receptors. It is completely absorbed to reach peak concentrations in the range of 1000 ng/mL in 6 hours. Quetiapine has a half-life averaging 5 hours. It is 80% protein bound. Quetiapine is cleared by CyP 2C9 and 2C19 metabolism to inactive desalkyl amine metabolites. Quetiapine is likely to produce liver function abnormalities in a small number of patients who receive the drug; evaluation of liver function should be performed regularly on patients prescribed quetiapine.

Antimetabolites

Methotrexate and thiopurines are antimetabolites and representative of several drugs that interrupt cell cycling that

TABLE 33-11 Key Pharmacokinetic Parameters of Methotrexate

Drug	Minimum Toxic Concentration at 24 hrs After Dose (μmol/L)	Minimum Toxic Concentration at 48 hrs After Dose (μmol/L)	Minimum Toxic Concentration at 72 hrs After Dose (μmol/L)	Average Half-Life at 100 μmol/L (hr)	Average Half-Life at 10 μmol/L (hr)	Average Half-Life at 1 μmol/L (hr)
Methotrexate	>10	>1	>0.1	1.8	8.4	>10

are used to treat neoplastic diseases; their use may require TDM.

Methotrexate

Methotrexate has proved useful in the (1) management of acute lymphoblastic leukemia in children; (2) management of choriocarcinoma and related trophoblastic tumors in women[36]; (3) management of carcinomas of the breast, tongue, pharynx, and testes; (4) maintenance of remission in leukemia; and (5) treatment of severe, debilitating psoriasis. High-dose methotrexate administration followed by leucovorin rescue is effective in treatment of carcinoma of the lung and osteogenic sarcoma. Intrathecal administration is effective in treating meningeal leukemia or lymphoma. Table 33-11 lists pharmacokinetic parameters for methotrexate.

Methotrexate inhibits DNA synthesis by decreasing availability of pyrimidine nucleotides. Methotrexate competitively inhibits the enzyme dihydrofolate reductase, thus decreasing the concentrations of the tetrahydrofolate essential to the methylation of the pyrimidine nucleotides and consequently the rate of pyrimidine nucleotide synthesis. Leucovorin, a folate analog, is used to rescue host cells from methotrexate inhibition; as a synthetic substrate for dihydrofolate reductase, leucovorin administration allows resumption of tetrahydrofolate-dependent synthesis of pyrimidines and reinitiation of DNA synthesis. Methotrexate is a nonspecific cytotoxin, and prolongation of blood levels appropriate to killing tumor cells may lead to severe, unwanted cytotoxic effects such as myelosuppression, gastrointestinal mucositis, and hepatic cirrhosis.

Serum concentrations of methotrexate are commonly monitored during high-dose therapy (>50 mg/m^2) to identify the time at which active intervention by leucovorin rescue should be initiated. Criteria for blood concentrations indicative of a potential for toxicity after single-bolus, high-dose therapy are as follows:[115]

1. Methotrexate concentration greater than 10 μmol/L 24 hours after dose.
2. Methotrexate concentration greater than 1 μmol/L 48 hours after dose.
3. Methotrexate concentration greater than 0.1 μmol/L 72 hours after dose.

Characteristically, blood concentrations are monitored at 24, 48, and 72 hours after the single dose, and leucovorin is administered when methotrexate levels are inappropriately high for a postdose phase. The route of elimination for methotrexate is primarily renal excretion. During the period of high blood levels, particular attention must be paid to maintaining output of a large volume of alkaline urine. The pK_a of methotrexate is 5.5; thus small decreases in urine pH result in significant reduction in its solubility. Keeping urinary pH alkaline diminishes the risks of intratubular precipitation of the drug and obstructive nephropathy during the treatment period. Monitoring blood levels therefore provides the basis for decisions for timing of initiation and continuance of leucovorin treatment and for managing urinary pH.

Methotrexate has been measured in biological specimens using a wide variety of techniques. RIA and the folate reductase inhibition techniques have been used, but nonisotopic immunoassays are now the method of choice.[3] Liquid chromatographic procedures have also been developed to allow for co-analysis of the drug and its metabolites.[7]

Thiopurines

The thiopurine drug mercaptopurine, and its prodrug azathioprine, are used as to treat neoplasias such as leukemia. Thiopurines are metabolized by thiopurine *S*-methyltransferase (TPMT) to form *S*-methylthiopurines, which are further metabolized to *S*-methylthiopurine nucleosides, the very short-lived active agent. Approximately 1% of Caucasians are homozygous for an allele variant of TPMT that expressed no activity. Patients expressing minimal TPMT activity shunt thiopurine to an alternate metabolic pathway, resulting in accumulation of thiopurine nucleosides, which cause cytotoxicity. Patients at risk for thiopurine intoxication can be identified by monitoring TPMT phenotypic enzymatic activity,[146] genotype,[147] or thiopurine nucleotide concentration.[106] Table 33-11 lists pharmacokinetic parameters for thiopurines.

Other Antimetabolites

For various reasons, purine and pyrimidine drugs have not been routinely monitored outside of clinical trials. Cytosine arabinoside; 5-fluorouracil; 5-fluorodeoxyuridine and its monophosphate, 5-azacytidine; and 2,2 difluorodeoxycytidine, which are all antimetabolites like methotrexate, have been extensively studied. Analytical methods have also been developed, but little relationship between circulating blood level and therapeutic efficacy has been found to justify

routine monitoring. Alkylating agents such as cyclophosphamide are metabolically converted to active compounds with lifespans of only seconds before they interact with tissue and are destroyed. Measurement of active metabolite would be extremely useful but is obviously impractical. Actinomycin and doxorubicin have toxic effects (bone marrow suppression and dermatitis) that are both immediate and long acting and that appear to relate not to a circulating blood concentration but to dose mass and length of exposure. Definition of specific dosing regimens for these drugs is currently of more concern than is control of circulating concentration. Cisplatin, easily measurable by platinum analysis, causes renal toxicity that may be related to both blood levels and length of exposure, although monitoring is not common.

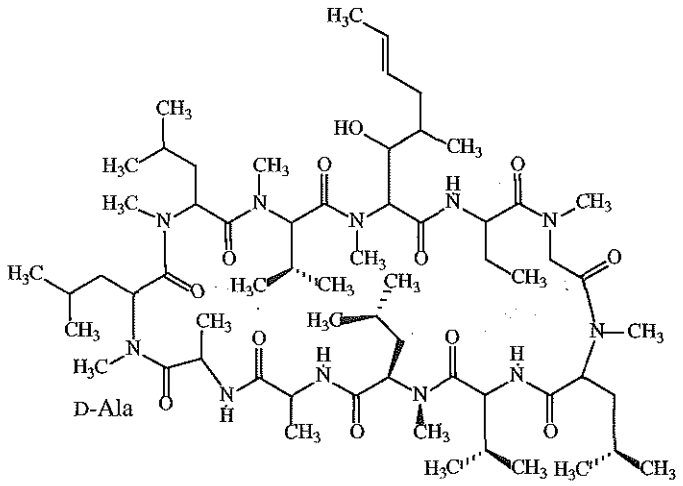
IMMUNOSUPPRESSANTS

Immunosuppressants are drugs capable of suppressing immune responses. They are used to treat autoimmune disease, allergy, multiple myeloma, and chronic nephritis, and in organ transplantation. For example, immunosuppressants that are used to provide maintenance immunosuppression in solid organ and bone marrow transplant patients include cyclosporine, everolimus (Ever), mycophenolic acid (MPA), Siro, and Tac (Figure 33-13).

History of Immunosuppressant Therapy

Patterns of use of immunosuppressive drugs in transplant patients have changed through the decades.[139] From 1954 to 1962, referred to as the "Experimental Era," there were few transplants performed; the incidence of acute rejection during the first year following transplant surgery was 80% and the 1-year graft survival was 40%, and the search was on to find acceptable immunosuppression techniques. The successful use of azathioprine combined with corticosteroid from 1962 to 1983, the "Azathioprine Era," made widespread kidney transplantation possible. The rates and severity of acute rejection (65% acute rejection) were high, as was the graft loss rate (60% with 1-year survival). The "Cyclosporine Era" (1983 to 1995) provided for significant improvement of outcomes (45% acute rejection, 85% with 1-year survival), and routine transplantation of organs other than kidneys was instituted with a relatively fixed drug regimen. The recognition, in early clinical trials, that cyclosporine has a narrow therapeutic index and highly variable pharmacokinetics in renal transplant patients led to the development of immunoassay[14] and HPLC methods for quantification.[89] It was during this era that therapeutic drug monitoring of cyclosporine became a standard of practice, and set the stage for the evolution of this practice for the other major maintenance immunosuppressants. Introduction of Tac in 1994 and mycophenolate mofetil in 1995 opened the most recent era. The introduction of Siro in 1999 and Ever in 2004 provided a major addition to this era.

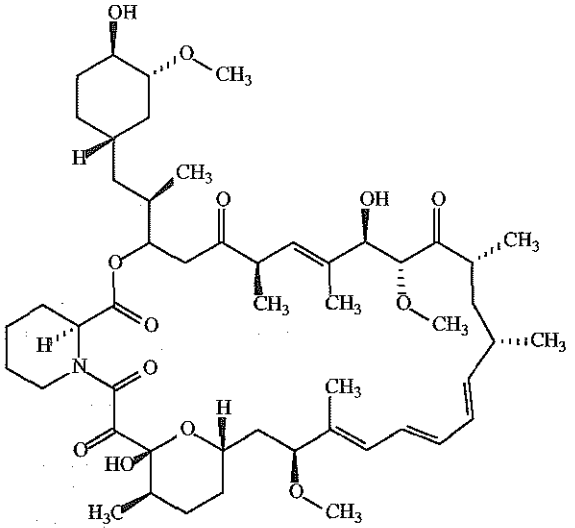
Drug regimens used in the current era for maintenance immunosuppression vary widely according to the transplanted organ, especially the choice and dosing strategy for calcineurin inhibitors (cyclosporine or Tac).[22,55,56,58,86] In 2002 the United Network for Organ Sharing (UNOS) reported that the following combinations of maintenance immunosuppressants were used in newly transplanted patients: (1) Tac + MPA + corticosteroids; (2) cyclosporine + Siro + corticosteroids; (3) cyclosporine + MPA + corticosteroids; and (4) Tac + Siro + corticosteroids. (It is anticipated that Ever can be substituted for Siro.) All of these drugs have narrow therapeutic indices and their pharmacokinetics are highly variable in transplant patients, particularly in the early posttransplant period. They require close supervision with TDM guiding dosage adjustments to minimize the risks of opportunistic infections, lymphoproliferative disease, and serious drug-specific toxicities from excessive immunosuppression and rejection from too little immunosuppression.



Corticosteroids are dosed according to empiric guidelines whereas cyclosporine, Tac, MPA, Siro, and Ever are dosed to achieve and maintain target concentrations in blood (cyclosporine, Tac, Siro, Ever) or plasma (MPA). In today's practice—which often includes reduction of the calcineurin inhibitor, dosing, and target concentrations or elimination of corticosteroid within the first posttransplant year—the demand for tighter and better control of immunosuppressant concentrations is heightened requiring more involvement of laboratorians to help in the demanding process to provide optimal immunosuppression.

Cyclosporine

Cyclosporine, proprietary names *Sandimmune* (cyclosporine) and *Neoral*, is a cyclic peptide composed of 11 amino acids, some of novel structure, isolated from the fungus *Trichoderma polysporum* (Figure 33-13). The compound has been shown effective in suppressing acute rejection in recipients of allograft organ transplants. Cyclosporine is approved for use in renal, cardiac, hepatic, pancreatic, and bone marrow transplants.



The activation and proliferation of T lymphocytes are considered to be the basic cellular immune responses leading ultimately to rejection of transplanted tissue in the absence of effective immunosuppression. An important effect of T cell activation is production of the Ca^{2+}/calmodulin-activated form of the serine/threonine phosphatase calcineurin. The latter is responsible for the activation and nuclear translocation of a number of transcription factors, such as nuclear factor of activated T (NFAT) cells.

Cyclosporine provides maintenance immunosuppression by inhibition of the activation of T lymphocytes via a multifaceted mechanism.[105] The drug, a fat soluble 11 amino acid cyclic polypeptide, crosses the lymphocyte membrane freely where it forms a pharmacologically active complex with the intracellular immunophilin receptor cyclophilin. This complex, but not cyclosporine by itself, inhibits the Ca^{2+}/calmodulin-activated form of serine/threonine phosphatase calcineurin, thereby inhibiting the activation of NFAT cells. The latter action is considered to be the key step

that leads to several important effects of cyclosporine on the activated T lymphocytes. Although cyclosporine inhibits the peptidylprolyl isomerase activity of cyclophilin, this action has not been shown to affect T cell activation.[109]

Inhibition of activation of NFAT mediated by cyclosporine leads to the downregulation of transcription of cytokine genes for cytokines such as IL-2, IL-3, IL-4, and IL-12; inflammatory mediators such as TNFα; and growth factors such as granulocyte and/or macrophage colony stimulating factor (see Chapter 22). Inhibition of calcineurin by the cyclosporine/cyclophilin complex produces other important intracellular effects that contribute to the overall immunosuppressive effect. The intracellular mechanism(s) by which cyclosporine produces side effects—such as the acute nephrotoxic effects including reduced renal blood flow, afferent arteriolar vasoconstriction, decreased glomerular filtration rate, and increased renal vascular resistance—remains unknown. It is likely that inhibition by cyclosporine/cyclophilin of calcineurin-mediated processes in kidney tissue is responsible for these effects.

Absorption of cyclosporine in the form of Sandimmune is highly variable, ranging from 5% to 40%. Whole-blood concentration correlates with the degree of immunosuppression and toxicity, but there is a poor relationship between dose and blood concentration. A microemulsion form of cyclosporine, Neoral, has more reproducible absorption—averaging 40%—and exhibits better correlation between dose, blood level, and clinical response.[60] In addition to

Neoral and Sandimmune, there are three generic forms of cyclosporine approved for use by the U.S. Food and Drug Administration (FDA). Although considered therapeutically equivalent to Neoral, the excipients differ from that of Neoral or Sandimmune. The chemical structure of these is equivalent to that of cyclosporine; however, close therapeutic drug monitoring is recommended when switching from one formulation to another in view of the very limited availability of peer-reviewed, published data on the generics.[108]

Immunosuppression requires trough whole-blood concentrations of at least 100 ng/mL. A consensus report notes that trough whole-blood concentrations exceeding 600 ng/mL were associated with hepatic, renal, neurological, and infective complications.[64] Strategies for reducing the toxicity of cyclosporine and other immunosuppressive drugs have been published that suggest that therapeutic trough blood concentrations of cyclosporine for renal transplants are 100 to 300 ng/mL, whereas 200 to 350 ng/mL is used as the target concentration for cardiac, hepatic, and pancreatic transplants.[126] Simultaneous immunosuppression with low-dose prednisone and either MPA or Siro allows the patient to enjoy a good response to cyclosporine at lower concentration; some renal transplant patients obtain a satisfactory response with trough cyclosporine levels of 70 ng/mL.[73]

The limitations of trough concentration monitoring of cyclosporine were recognized by Kahan, who showed that the dose interval AUC of the drug provided a more precise estimate of drug exposure and better predictive performance for estimation of risks for acute rejection or toxicity.[62] However, the impracticality of measurement of a full AUC using a series of samples collected over the 12-hour dose interval prevented this more accurate and precise determination of cyclosporine exposure from ever becoming a widely used monitoring test. A new approach is based on the association of most of the variability in cyclosporine pharmacokinetics during the first few hours following oral administration. This approach measures either the area under the blood cyclosporine concentration-time curve in the first 4 hours postdose[6] or measures the blood cyclosporine concentration at 2 hours postdose, known as C2 monitoring.[20] The latter approach promises to provide for more precise targeting of cyclosporine exposure.[86]

Cyclosporine is slowly absorbed, and peak concentrations are reached in 4 to 6 hours. Cyclosporine is 90% protein bound and concentrated in erythrocytes.[149] The degree of concentration in erythrocytes is temperature dependent in vitro; for this reason, measurement of plasma concentration is not recommended.[54] The optimal specimen for analysis is whole blood. The elimination profile of cyclosporine is biphasic. An early elimination phase with an apparent half-life that typically ranges from 3 to 7 hours is followed by a slower elimination phase with an apparent half-life ranging from 18 to 25 hours. The volume of distribution is 17 L/kg. Cyclosporine undergoes extensive metabolism by CyP 3A4. Many of the 31 known metabolites of cyclosporine are inactive.[151] One of the major metabolites, hydroxylated at the number 1 amino acid, retains approximately 10% of the immunosuppressive activity of the parent compound.

Many drugs alter the disposition of cyclosporine. Drugs that inhibit cytochrome P450 3A enzyme activity and block P-glycoprotein (Pg) have been found to decrease cyclosporine metabolism and reduce the barrier to absorption from the gastrointestinal tract, thereby causing increased blood concentration. The latter was recognized in 1999 as very important, together with CyP 3A, as a natural barrier to absorption of xenobiotics.[4,47] Examples include the calcium channel blockers verapamil, diltiazem, and nicardipine; azole antifungal drugs fluconazole, itraconazole, voriconazole, and ketoconazole; and antibiotics, such as erythromycin. All prolong metabolism of cyclosporine and reduce the barrier to absorption sufficiently to increase the risk of nephrotoxicity.[84] Co-administration of phenytoin, phenobarbital, carbamazepine, and rifampin results in induction of CyP 3A enzymes and Pg, which, respectively, increase the rate at which cyclosporine is metabolized in the gastrointestinal tract and liver, and the countertransport of the drug, thereby reducing significantly the bioavailability of the parent drug.[64] Intravenous administration of sulfadimidine and trimethoprim decreases cyclosporine concentrations.

The first procedure available for analysis of cyclosporine was an RIA developed by Sandoz Pharmaceuticals, the producer of cyclosporine. This immunoassay exhibits approximately 30% cross-reactivity with inactive metabolites, and the test is now considered obsolete. Nonisotopic immunoassays have been developed for whole-blood analysis.[27,79,86] HPLC methods have been developed and are used now by many laboratories.[89] A practical HPLC tandem mass spectrometry method is included on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

Everolimus

Ever, proprietary name *Certican* and also known as *SDZ RAD*, is a rapamycin analog with potent immunosuppressive activity when used in conjunction with CyA. Structurally, Ever is a semisynthetic lipophilic macrocyclic lactone macrolide (Figure 33-13). Like Siro (see below), Ever forms a complex with intracellular immunophilin FK-BP12 that modulates the immune response by combining with the specific cell-cycle regulatory protein mTOR and inhibiting its activation. This inhibition results in suppression of cytokine-driven T lymphocyte proliferation, inhibiting the progression from the G_1 to the S phase of the cell cycle. Ever is metabolized through oxidation by CyP 3A in the gastrointestinal tract and liver. At least 20 metabolites have been identified.[97]

Cyclosporine inhibits the metabolism of Ever, requiring Ever dose reduction when co-administered with CyA; simultaneous administration of CyA and Ever is expected to be the usual approach to immunosuppression. Ever does not affect CyA metabolism. The primary side effect of concern with Ever therapy is hyperlipidemia.[31]

Ever is administered orally as an oral microsuspension. Ever is rapidly absorbed from the gastrointestinal tract, with the average time to reach maximal concentration in whole blood of about 3 hours.[98] Low bioavailability is predicted by extensive intestinal and hepatic metabolism by CYP3A and countertransport by the multidrug efflux pump Pg in the gastrointestinal tract. This absorption barrier varies considerably from patient to patient and within-patient and is the site of clinically important drug-drug and drug-food interactions. The apparent elimination half-life of Ever is 24 hours. Proportionality between dose and blood concentration increases with a greater dose,[31] and higher dosing appears to increase bioavailability. Steady-state trough blood concentration on a 3 mg/day dose in an adult is likely to be in the range of 3 to 20 ng/mL.[31,97] A detailed description of an HPLC/MS/MS method to quantify Ever blood concentration is included on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF), proprietary name *CellCept*, is the 2-morpholinoethyl ester prodrug form of the active immunosuppressant MPA (Figure 33-14). The latter is a fermentation product of several *Penicillium* species that has antifungal, antibacterial, antitumor, and immunosuppressive activity in animal models.[111] Following the demonstration of its immunosuppressive efficacy in human renal transplant patients and in combination with cyclosporine and corticosteroids, formal clinical trials were conducted. In 1995 MMF was approved by the U.S. FDA for this use.

MPA is a reversible and uncompetitive inhibitor of inosine monophosphate dehydrogenase (IMPDH). A very important characteristic of proliferating lymphocytes is the greatly increased rate of de novo purine biosynthesis. The sustained and markedly increased rate of guanine nucleotide production catalyzed by IMPDH is the rate limiting step in de novo purine biosynthesis that cannot be provided by the salvage pathway in proliferating lymphocytes.[33] Thus the proliferative response of activated T cells is dependent on a continuous and increased supply of intracellular guanine nucleotide pool. T cell proliferation is arrested by the suppression of guanine nucleotide production when IMPDH is inhibited by MPA. The mechanism of action whereby MPA produces its immunosuppressive effect in proliferating T lymphocytes is thus clearly distinct from that of the calcineurin inhibitors: cyclosporine or Tac, and Siro.

MMF is rapidly hydrolyzed by widely distributed esterases in blood and tissues to produce MPA. The rate limiting step in the clearance of MPA is its conversion to the phenolic glucuronide metabolite MPAG (Figure 33-14) via

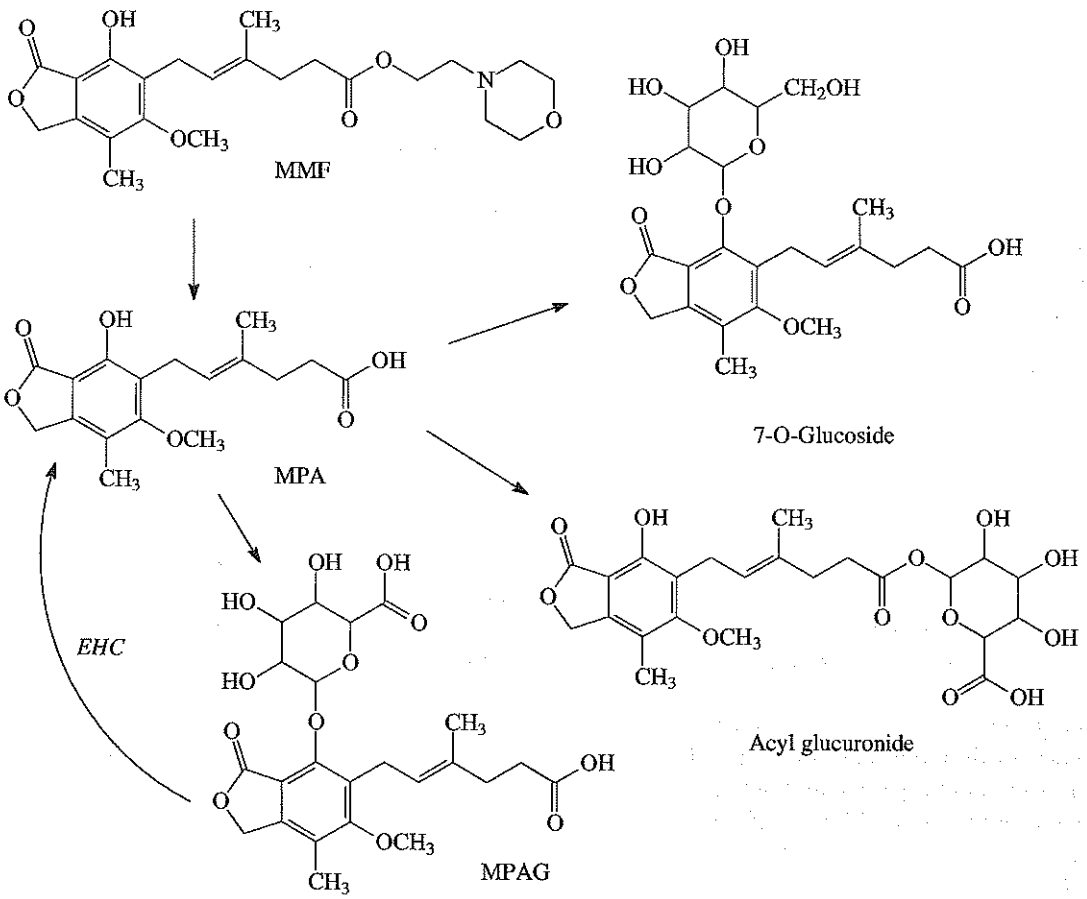

Figure 33-14 Chemical structures and metabolic pathways of mycophenolate mofetil (MMF), mycophenolic acid (MPA), and mycophenolate glucuronide (MPAG).

the catalytic action of UGT in the liver, gastrointestinal tract, and possibly other tissues, such as kidney. MPAG is the primary metabolite of MPA and is pharmacologically inactive.[67] The acyl glucuronide and 7-O-glucoside are metabolites that are produced in much smaller quantities than either MPA or MPAG.[129] The glucoside metabolite has no pharmacological activity, but the acyl glucuronide is under evaluation for its potential toxic effects.[148] MPAG is cleared by the kidney and accumulates to as much as several hundred–fold higher plasma concentration as the steady-state trough concentration of MPA in uremic patients.[123-125]

MPA usually reaches maximal concentrations within an hour of the time of oral administration of MMF.[13] Distribution of the drug is rapid and essentially complete in most patients within 2 to 3 hours of administration.[13] In whole blood, >99.9% of the drug is in the plasma compartment.[100] MPA's clearance is affected by (1) glucuronidation, (2) enterohepatic circulation (EHC), and (3) the quantity of its free fraction. EHC is considered to be a significant contributor to the dose interval kinetics of MPA, especially the post-distribution phase of the concentration-time curve. The contribution of EHC to the MPA AUC is about 37%, ranging from 10% to 61%, based on the effect of concomitant administration of cholestyramine.[13] The appearance of a secondary MPA concentration peak anywhere from 4 to 12 hours following the morning dose of MMF is believed to result from EHC.

MPA is avidly and extensively bound to human serum albumin. In stable transplant patients, the MPA free fraction ranges from 1% to 3%.[100] When one or more of the following conditions are present, the MPA free fraction will increase significantly:

1. Early poor kidney function in renal transplant patients
2. Chronic renal failure
3. Low serum albumin concentration
4. Hyperbilirubinemia
5. Liver transplant patients in the early posttransplant period

Increased free fraction will cause an increased clearance of MPA, resulting in lower total MPA concentrations that return to baseline values when the condition that caused the change in free fraction becomes normal.[124] In chronic renal failure, however, the total MPA concentration is often within the guidelines for effective immunosuppression, but the free concentrations can be substantially elevated—placing the patient at increased risk for overimmunosuppression.[54,65,83] It is hypothesized that chronic uremia causes reduction in the intrinsic clearance that results in zero order kinetics for MPA clearance.

The primary sites and effects of drug-drug interactions involving other medications and MPA are likely to be decreased absorption in the gastrointestinal tract, inhibition of enterohepatic cycling, and inhibition of transport of the primary phenolic glucuronide metabolite. Meal consumption just before oral intake of MMF delays absorption, causing a reduction in the maximal concentration by about 25%. Administration of antacids containing magnesium and aluminum hydroxides has been reported to reduce peak concentration of MPA by 33% and AUC by 17%. The two interactions with the greatest reported effects are cholestyramine and ferrous sulfate.[13,85] Cholestyramine produces a 40% reduction in the MPA AUC when co-administered with MMF. The common iron supplement ferrous sulfate lowers the MPA AUC by about 90%. Long-term effects of this drug interaction are under investigation. It has been suggested that corticosteroids cause enhanced clearance of MPA via induction of UGT activity.[15] This is based on the observed 33% increase in the dose-corrected MPA trough concentration in a cohort of stable renal transplant patients at 12 months, following corticosteroid withdrawal, compared with the value at 6 months during maintenance therapy with corticosteroids.[15] Further investigation will be required to establish whether or not there is a direct cause-effect relationship in transplant patients. Corticosteroids have been shown to induce UGT activity in animal models. Inhibition of transport of MPAG from liver into bile is the presumed mechanism for the significant lowering of MPA concentration and raising of MPAG concentration by concomitant cyclosporine.[140] This drug-drug interaction results in MPA AUC values, adjusted for MMF dose, that are approximately 45% higher in patients on concomitant Tac versus those on concomitant cyclosporine.

HPLC methods with UV detection for MPA quantification are in common use in clinical pharmacokinetic studies and in clinical laboratories.[5,138] An immunoassay has been developed and is in routine use in centers outside the United States.[144] Validated HPLC assays with mass spectrometric detection have been developed and are particularly useful for the accurate measurement of free MPA concentration.[125] A new method that uses IMPDH, the natural target receptor of MPA, is in development.[28] Inhibition of IMPDH activity by MPA in an aliquot of patient serum or plasma is the basis for this method.

Sirolimus

Siro, proprietary name *Rapamune,* and formerly known as Rapamycin, is a macrocyclic antibiotic with immunosuppressive activity.[57] It is a fermentation product of the actinomycete *Streptomyces hygroscopicus,* which was isolated from soil samples collected on Rapa Nui (Easter Island) following a search for novel antifungal agents. Structurally, Siro is a lipophilic macrocyclic lactone composed of a 31-membered macrolide ring (Figure 33-13). It was shown to possess antifungal, antitumor, and immunosuppressive activity in animal model studies.[96] Subsequently, following discovery of its efficacy for the prophylaxis of acute rejection in renal transplant patients, formal clinical trials were undertaken; in 1999 Siro was approved for this indication by the U.S. FDA.

The complex of Siro and the intracellular immunophilin FK-BP12 modulates the immune response by combining with the specific cell-cycle regulatory protein mTOR and

inhibiting its activation. This inhibition results in suppression of cytokine driven T lymphocyte proliferation, inhibiting the progression from the G_1 to the S phase of the cell cycle.[75] Metabolism of Siro by the human body is driven by oxidative metabolism by CyP 3A in the gastrointestinal tract and liver. There are at least 7 metabolites characterized as 41-O- and 7-O-demethyl, several hydroxy, hydroxy-demethylated, and didemethylated Siro.

Siro is administered orally as an oral solution in a vehicle containing a combination of phosphatidylcholine, propylene glycol, monoglycerides, ethanol, soy fatty acids, ascorbyl palmitate, and polysorbate 80 with a Siro concentration of 1 mg/mL. A 1 mg tablet formulation was recently approved, but this formulation is not bioequivalent to the oral solution. However, the two are clinically equivalent at a 2-mg dose based on comparable rates of efficacy failure graft loss or death. Siro is rapidly absorbed from the gastrointestinal tract, with the average time to reach maximal concentration in whole blood of about 2 hours.[156] The average bioavailability of Siro is 15%.[153] The low bioavailability is attributable to extensive intestinal and hepatic metabolism by CYP3A and to countertransport by the multidrug efflux pump Pg in the gastrointestinal tract.[95] This absorption barrier varies considerably from patient to patient and within-patient and is the site of clinically important drug-drug and drug-food interactions.

Siro distributes primarily into blood cells (95%), with only 3% and 1% distributing into plasma, lymphocytes, and granulocytes, respectively.[152] The extensive and avid binding of Siro to the ubiquitously distributed intracellular FK-binding proteins accounts for the high blood to plasma Siro concentration ratio. Approximately 2.5% of the Siro within the plasma fraction is unbound.[95]

The relationship between Siro whole blood trough concentrations has been investigated in renal transplant patients who received concomitant full dose cyclosporine and corticosteroid therapy. According to this study, the minimum effective Siro concentration—below which there is a significant increase in risk for acute rejection—is 4 to 5 ng/L.[63] The threshold concentration of 13 to 15 ng/L was identified, above which the risks for the concentration-related side effects of thrombocytopenia (<100,000 platelets/mm^3), leukopenia (<4000 leukocytes/mm), and hypertriglyceridemia (>300 mg/dL serum triglycerides) are increased.[63]

HPLC methods with MS, MS/MS, and UV detection have been validated and are in use in laboratories worldwide.[59,136] An immunophilin binding assay was developed for Siro measurement[25] and an investigational microparticle enzyme immunoassay was used in two phase III clinical trials.[95] Currently, there is no available automated immunoassay, although assays of this type are in development.

Tacrolimus

Tac, proprietary name *Prograf* and formerly known as *FK506,* is a macrolide lactone isolated from *Streptomyces tsukubaensis* in 1984 and is a potent immunosuppressant, which consists of a 23-membered carbon ring and a hemiketal-masked α,β-diketoamide function (Figure 33-13). Tac is approved for prophylaxis of organ rejection in patients receiving allogeneic liver transplants and for use as an immunosuppressant in kidney transplantation. This potent immunosuppressant has been used effectively in other solid organ transplant patients for prevention of graft-versus-host-disease in allogeneic stem cell transplant recipients and in pancreatic islet transplantation.

As with cyclosporine and Siro, Tac exerts its immunosuppressive effect following the formation of a complex with immunophilins. The complex of Tac and FK-BP12 in lymphocytes suppresses the synthesis of cytokines and inflammatory mediators by the same mechanisms (see Cyclosporine section for details and references).

Cytochrome P450 3A is primarily responsible for Tac metabolism and nine metabolites have been isolated from human blood and rat bile, or produced in vitro by human or animal liver microsomes. Tac metabolites in the blood of liver and kidney transplant patients totaled 42% to 45% of the Tac concentration. All of the metabolites, except for 31-O-desmethyl Tac, a minor Tac metabolite, have little immunosuppressive activity. The latter has in vitro immunosuppressive activity comparable with that of the parent drug. The total immunosuppressive activity of the metabolites is therefore negligible in transplant patients. However, in liver transplant patients with hyperbilirubinemia, there can be significant high bias in the immunoassay results because of metabolite accumulation that results from impaired bile clearance.[76]

Tac is most often administered by the oral route in capsules as a solid dispersed in hydroxypropylmethylcellulose. A solution for injection is available. The absorption from the small intestine is generally low, averaging 25%—but highly variable from patient to patient, ranging from 4% to 93%—and changes with time following transplant surgery.[142] Low Tac bioavailability, such as cyclosporine and Siro, is due to the presence of CyP 3A4/5 and the multidrug efflux pump Pg in the small intestinal enterocytes. The combination of this drug metabolizing enzyme and the drug efflux pump are thought to form a natural barrier to the absorption of xenobiotics in the gastrointestinal tract. The extensive interpatient range of bioavailability is likely due to the wide range of CYP3A4/5 catalytic activity and the amount of Pg per unit of weight of small intestine. Since many other drugs are substrates for these two systems, the gastrointestinal tract is an important site for many drug-drug interactions involving Tac.[17]

The distribution in blood is characterized by an extensive uptake by cells. The whole blood–to-plasma ratio varies from 15 to 35. The high affinity of Tac for FK-binding proteins and their rich presence in blood cells account for this distribution. Approximately 99% of Tac in plasma is bound to proteins, primarily α_1-acid glycoprotein, lipoproteins, albumin, and globulins.[154] The major route of elimination is

TABLE 33-12 Pharmacokinetic Parameters of Immunosuppressant Drugs

Drug	Minimum Effective Concentration (MEC) (ng/mL)	Minimum Toxic Concentration (MTC)* (ng/mL)	Average Half-Life (hr)	Average Volume of Distribution (L/kg)	Average Oral Bioavailability (%)	Average Protein Binding (%)	Important Metabolizing Enzymes

fecal excretion of metabolites. Elimination half-life of Tac is variable. Average half-life values of 12 hours and 19 hours have been reported in liver and renal transplant patients. Tac pharmacokinetic parameters are summarized in Table 33-12.

As for cyclosporine and Siro, many drugs interact with Tac by either inducing the production of CyP 3A4/5 and Pg or by competitively blocking the Tac binding site on these. A comprehensive review on this subject has been published.[17]

The relationship between Tac dose, trough blood concentration, and clinical outcomes—including acute rejection, nephrotoxicity, and toxicity requiring dose reduction—was investigated in a prospective multicenter study in liver transplant patients.[90] A significant inverse correlation between Tac trough blood concentration and the risk of acute rejection during the first week following liver transplantation was shown using logistic regression analysis. Nephrotoxicity and other side effects were also significantly correlated with increasing Tac trough blood concentrations during this time period. Receiver operator characteristic curve analyses showed that Tac trough blood concentrations could differentiate between toxicity and nonevents.[143]

A number of specific and sensitive HPLC/MS methods have been developed.[2,17,71,133,135] An immunoassay for Tac measurement is also available.

CLINICAL APPLICATIONS

Three case studies that apply the clinical principles and the pharmacology data described in this chapter are presented on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/. They present typical problems the clinician and clinical laboratorian are faced with in daily practice.

CHAPTER 34

Clinical Toxicology*

William H. Porter, Ph.D.

Toxicology is a broad, multidisciplinary science whose goal is to determine the effects of chemical agents on living systems. *Clinical toxicology* is a division of toxicology and is defined as the analysis of drugs, metals, and other chemical agents in body fluids and tissue for the purpose of patient care. Such analyses are often necessary for the diagnosis and management of acute drug overdose and acute exposure to chemicals of unknown origin from the patient's environment.

This chapter focuses primarily on the analytes a laboratorian encounters in clinical toxicology and on analytical techniques used to measure them. Because a comprehensive discussion of all the aspects of toxicology is beyond the scope of this chapter, the clinical significance and toxicity of only a select number of common drugs, drugs of abuse, and other chemicals are discussed. For additional information, readers are referred to several excellent texts on toxicology, including *Clinical Management of Poisoning and Drug Overdose,*[185] *Ellenhorn's Medical Toxicology: Diagnosis and Treatment of Human Poisoning,*[136] *Casarett and Doull's Toxicology: The Basic Science of Poisons,*[247] *Clinical Toxicology of Commercial Products,*[177] *Goodman and Gilman's The Pharmacologic Basis of Therapeutics,*[189] and *Goldfrank's Toxicologic Emergencies,* and to Chapters 30 and 35 where some of the more toxic metals are discussed.[75]

BASIC INFORMATION

In practice, it is not possible nor necessary to test for all of the hundreds or thousands of clinical toxins that may be encountered. In reality up to 24 drugs or agents account for 80% or more of intoxication treated in most emergency departments.[328,471] Moreover, some drugs are encountered very infrequently in some locations but with relatively high frequency in others. For example, phencyclidine (PCP) use is almost nonexistent in some areas but is responsible for a relatively high number of intoxications in a few large metropolitan cities. Thus the scope of clinical toxicology testing provided by the laboratory will depend on the pattern of local drug use and on the available resources of the institution and should be developed in consultation with the appropriate clinical staff.[270]

The value of drug and/or substance testing (screening) is well established (1) in the workplace, (2) for some athletic competitions, (3) to monitor drug use during pregnancy, (4) to evaluate drug exposure and/or withdrawal in newborns, (5) to monitor patients in pain management and drug abuse treatment programs, and (6) to aid in the prompt diagnosis of toxicity for a select number of drugs or agents for which a specific antidote or treatment modality is required (Table 34-1). In many other instances of drug toxicity, the value of drug screening, especially on an emergency basis, is more controversial.[65,139,239,314,388] It is argued that often drug toxicity is recognizable based on history and clinical signs and symptoms (see section on Toxic Syndromes), that treatment is general and supportive (Box 34-1) and therefore not influenced by results of drug screens, and that drug screen results often are not available soon enough to add valuable information. However, the clinical history is not always available or reliable, not all patients present with symptomatology clearly recognizable as drug or substance intoxication, and symptomatology may be complicated and confusing in instances of multiple drug overdose.[198,239,256,365] Moreover, it is clearly important to rule in or rule out drug toxicity as a possible etiology for patients with altered mental status or coma of unknown origin or for patients with seizures. For instance, a negative drug screen is helpful in the differential evaluation of a comatose patient eventually diagnosed with meningitis. For other patients, the results of drug testing may confirm the diagnosis or be valuable for follow-up counsel-

*The author gratefully acknowledges original contributions by Dr. Tom P. Moyer, upon which portions of the chapter are based.

TABLE 34-1 Antidote or Specific Treatment for Intoxication

Toxin	Antidote/Treatment
Acetaminophen	*N*-Acetylcysteine (Mucomyst)
Aluminum	Deferoxamine
Anticholinergic agents	Physostigmine
Arsenic	Dimercaprol, 2,3-dimercaptosuccinic acid, D-penicillamine
Barbiturates	Charcoal hemoperfusion, multiple-dose oral activated charcoal, alkaline diuresis (phenobarbital only)
Benzodiazepines	Flumazenil
Beta-blockers	Glucagon
Calcium channel blockers	Calcium
Carbamazepine	Multiple-dose oral activated charcoal; charcoal hemoperfusion
Carbon monoxide	Oxygen (normobaric or hyperbaric)
Cyanide	Amyl nitrite, sodium nitrite, sodium thiosulfate
Digoxin	Digibind (Fab fragments)
Ethylene glycol, methanol	Ethanol, hemodialysis, fomepizole (4-methylpyrazol)
Iron	Deferoxamine
Isoniazid	Pyridoxine
Isopropanol	Hemodialysis
Lead	Calcium disodium edetate, dimercaprol, 2,3-dimercaptosuccinic acid
Lithium	Hemodialysis
Mercury	Dimercaprol, 2,3-dimercaptosuccinic acid, D-penicillamine
Nitrites, nitrates	Methylene blue
Opioids	Naloxone
Organophosphate or carbamate insecticide	Atropine, pralidoxime (controversial for carbamates)
Salicylates	Bicarbonate, hemodialysis, alkaline diuresis
Theophylline	Multiple-dose oral activated charcoal, charcoal hemoperfusion
Tricyclic antidepressants	Bicarbonate

Data from references 9, 43, 137, 155, 268, 404.

BOX 34-1 General Supportive Measures in Treatment of Drug Overdose

1. Maintain airway, adequate ventilation, and oxygenation; provide tracheal intubation if required.
2. Maintain adequate cardiovascular function—intravenous crystalloid solutions and vasopressors (e.g., dopamine, norepinephrine) if required.
3. If comatose, administer glucose, thiamine, naloxone, and oxygen.
4. For seizures, administer diazepam, phenytoin.
5. Decontaminate gastrointestinal system—perform gastric lavage; induce vomiting if appropriate (syrup of ipecac); administer activated charcoal; administer cathartic (sodium sulfate, magnesium sulfate, or sorbitol); perform whole-bowel irrigation (isotonic polyethylene glycol electrolyte solution).

Data from references 43, 141, 155, 268, 404.

ing or treatment; in the latter instances, drug screens may not be required emergently.

Approaches to drug testing range from the provision of just a few specific tests (e.g., acetaminophen, salicylate, ethanol, digoxin, and iron) to additional targeted groups of drugs (e.g., stimulant panel and coma panel) or to a more comprehensive general drug screen that might include 100 or so drugs and/or substances. For all of these situations, it is important that the laboratory communicate with the physician concerning the scope (and limitation) of the service and the proper timing and selection of specimens; when possible, the laboratory should assist with interpretation of results. At a minimum, the laboratory request slip should clearly state the drugs that it has the capability of detecting. Otherwise, the report of a "negative" result for a drug screen could be misleading.

Clinical Considerations

To operate effectively, the laboratory requires a prerequisite amount of clinical information to guide ordering of the correct tests and to ensure that interpretation of results is complete and accurate. For example, the physician should provide the following information with the laboratory request:

1. The time and date of the suspected exposure and any indications from the patient or patient's family that might aid in identification of the toxin. The laboratory personnel must also have knowledge of the time that the specimens were collected.

2. Assessment of the physical state of the patient at the time of presentation, which should include the following:
   a. Vascular status (including measurement of blood pressure and pulse rate)
   b. Respiratory status (hypoventilation or hyperventilation)
   c. Temperature (presence of hypothermia or hyperthermia)
   d. Neurological status (determination of whether the patient is alert, comatose, or hyperactive or has neuropathy, cholinergic activity, or Babinski's sign)
   e. Cardiac status (determination of heart rate, electrocardiogram pattern, and QRS interval)
   f. Gastrointestinal (GI) status (presence of severe GI distress, vomiting, or diarrhea)

As described in the section Toxic Syndromes and discussed later in this chapter, each of these symptoms suggests a certain group of toxins. Such information is useful to guide test selection and interpretation of results. Realistically, physicians do not always have time or are not willing to provide such information. This clinical information is not necessary for test selection if the laboratory provides solely a broad-spectrum drug screen or provides symptom-related drug screens (coma panel and stimulant panel) selectable by the physician. However, such information still aids test interpretation. Because toxidrome assessment may be flawed by clinical inexperience, multidrug overdose, or delayed onset of action, an expert toxicology committee of the National Academy of Clinical Biochemistry discourages establishment of toxidrome-based drug screen panels.[491]

Analytical Considerations

Because of the wide range of drugs of interest, no single analytical technique is adequate for broad-spectrum drug detection. Therefore several analytical approaches in combination are generally required. These may include simple, inexpensive, and rapid spot tests; immunoassays (see Chapter 9); and chromatographic and/or mass spectrometric techniques (see Chapters 6 and 7), including thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), gas chromatography (GC), gas chromatography-mass spectrometry (GC-MS or GC-MS-MS), and liquid chromatography-mass spectrometry (LC-MS or LC-MS-MS).[442] Moreover, because of the innumerable drugs, metabolites, and endogenous substances that may be encountered, positive identification based on the results of a single analytical technique is generally not sufficiently definitive. Sound laboratory practice dictates the use of a second or confirmatory procedure that preferably is based on different analytical principles. Currently, GC-MS is the most widely used definitive confirmatory procedure. Confirmatory testing is mandatory for forensic drug testing (e.g., workplace drug testing).

Speed of analysis, or turnaround time (TOT), is a critical issue in clinical toxicology. A drug analysis that requires several hours to complete or that is not available at all hours of the day is of little value in a clinical emergency. On the other hand, a rapid test that provides false information could result in erroneous diagnostic and therapeutic decisions. Quantitative determinations in serum are important for acetaminophen, salicylate, ethanol, methanol, isopropanol, ethylene glycol, carbamazepine, phenytoin, valproic acid, phenobarbital, iron, transferrin (or unsaturated iron binding capacity), lithium, theophylline, and digoxin, and in whole blood for carboxyhemoglobin and methemoglobin. Results for these determinations should be available within 1 hour of specimen receipt.[491] For many other drugs, their serum concentration and the severity of toxicity do not correlate sufficiently to warrant obtaining quantitative information. In these cases, qualitative identification in urine is generally sufficient.

The proper selection of analytical methods and the interpretation of results requires a knowledge of the pharmacology and pharmacokinetics of the toxins of interest. For example, the potential hepatotoxicity of acetaminophen is related to the concentration of unmetabolized drug. Therefore, appropriate analytical methods for acetaminophen should measure only parent drug and not inactive metabolites. Moreover, quantitation of serum acetaminophen or salicylate before completion of the absorptive phase may be misleading in instances of overdose. Morphine is excreted in urine largely as morphine-3-glucuronide. The most sensitive detection of morphine necessitates a prior hydrolysis (acid or enzymatic) or methods that will directly measure the conjugate (e.g., immunoassay). Detection of the unique heroin metabolite, 6-monoacetylmorphine, distinguishes heroin use from ingestion of poppy seeds as the cause of a positive urine test for morphine.

Toxic Syndromes

Toxic syndromes ("toxidromes") are clinical syndromes that are essential for the successful recognition of poisoning patterns. A toxidrome is the constellation of clinical signs and symptoms that suggests a specific class of poisoning. The most important toxidromes are (1) anticholinergic, (2) cholinergic, (3) opioid and opioid withdrawal, (4) sedative-hypnotic and sedative-hypnotic withdrawal, and (5) sympathomimetic. Symptoms for these toxidromes are listed in Table 34-2.

Autonomic Nervous System

Many drugs commonly ingested in overdose cause dysfunction (agonistic or antagonistic) of the autonomic nervous system, the clinical consequences of which provide important clues to the clinician for diagnosis and treatment and also help guide the laboratory in the selection of appropriate tests.[135,256,276,328,404]

Biologically, the autonomic nervous system controls many physiological functions, including respiration, circulation, metabolism, digestion, secretions, and body temperature.[200] The *sympathetic* and *parasympathetic systems* are the two major divisions of the autonomic nervous system. In general, they are antagonistic (one stimulates while the other

TABLE 34-2 Symptoms of the Important Toxidromes

Toxidrome	Symptom
Anticholinergic	Agitation
	Blurred vision
	Choreoathetosis
	Decreased bowel sounds
	Dry skin
	Fever
	Flushing
	Hallucinations
	Ileus
	Lethargy/coma
	Mydriasis
	Myoclonus
	Psychosis
	Seizures
	Tachycardia
	Urinary retention
Cholinergic	Bradycardia
	Bronchorrhea
	Defecation
	Emesis
	Gastrointestinal distress (diarrhea)
	Lacrimation
	Salivation
	Urination
Opioid	Bradycardia
	Decreased bowel sounds
	Hypotension
	Hypothermia
	Lethargy/coma
	Miosis
	Shallow respirations
	Slow respiratory rate
Opioid withdrawal	Anxiety
	Diaphoresis
	Diarrhea with increased bowel sounds
	Fever
	Hypertension
	Irritability
	Lacrimation
	Muscle ache and spasm
	Mydriasis
	Nausea, vomiting
	Piloerection
	Restlessness
	Rhinorrhea
	Tachycardia
	Tachypnea
	Tremor
	Yawning
Sedative-hypnotic	Ataxia
	Blurred vision
	Confusion
	Delirium
	Diplopia
	Dysesthesias
	Hallucinations
	Hypotension
	Lethargy/coma
	Nystagmus
	Paresthesias
	Respiratory depression
	Sedation
	Slurred speech
Sedative-hypnotic, ethanol withdrawal	Agitation
	Anxiety
	Confusion
	Diaphoresis
	Dysphoria
	Fever
	Hallucinations
	Hypertension
	Insomnia
	Irritability
	Muscle spasm
	Nausea and vomiting
	Restlessness
	Seizures
	Tachycardia
	Tremor
Sympathomimetic	Agitation
	Diaphoresis
	Excessive motor activity
	Excessive speech
	Hallucinations
	Hypertension
	Hyperthermia
	Insomnia
	Restlessness
	Tachycardia
	Tremor

inhibits), and most organs are enervated by both, although not with equal tone. Norepinephrine is the neurotransmitter for postganglionic sympathetic fibers (adrenergic) that enervate skin, eyes, heart, lungs, GI tract, exocrine glands, and some neuronal tracts in the central nervous system (CNS). Physiological responses to activation of the adrenergic system are complex and depend on the type of receptor (α_1, α_2, β_1, β_2) activated, some of which are excitatory and others that have opposing inhibitory responses. These membrane-spanning adrenergic receptors are coupled to cytoplasmic surface GTP-binding regulatory proteins (G-proteins). Receptor activation results in GTP-mediated G-protein activation. The activated G-protein reacts with cell effectors, which may be enzymes such as adenyl cyclase or phospholipase C, or with multimeric transmembrane ion channels selective for Ca^{2+} or K^+. The resultant alterations (increase or decrease) in intracellular cAMP, Ca^{2+}, or K^+ ions leads to membrane hyperpolarization (inhibitory), depolarization (excitatory), or—for example—smooth muscle contraction. Other sympathetic neurotransmitters are dopamine, present in the extrapyramidal tracts in the CNS, and epinephrine, present in the adrenal medulla. Stimulation of the sympathetic nervous system produces CNS excitation (agitation, anxiety, tremors, delusions, and paranoia), headache, seizures, hypertension, mydriasis (dilated pupils), hyperpyrexia, and diaphoresis. In severe cases, hypotension, cardiac arrhythmias, and coma may occur. Examples of drugs that cause a *sympathomimetic* response include amphetamine, methhamphetamine, 3,4-methylenedioxymethamphetamine (MDMA), cocaine, PCP, lysergic acid diethylamide (LSD), ephedrine, pseudoephedrine, phenylpropanolamine, and caffeine. Some laboratories provide a stimulant drug screen panel designed to detect several of these drugs.

Acetylcholine is the neurotransmitter active in parasympathetic neurons (CNS and postganglionic peripheral), in autonomic ganglia (both sympathetic and parasympathetic), and in peripheral somatic nerves that enervate skeletal muscle (neuromuscular junction). Cholinergic responses may be subdivided into *muscarinic* (activated by muscarine) and *nicotinic* (activated by nicotine), depending on acetylcholine receptor type. Muscarinic receptors are G-protein coupled and are present in all autonomic ganglia, in postganglionic parasympathetic synapses, and in cortical and subcortical neurons. Muscarinic receptors are blocked by atropine. Nicotinic receptors are pentameric membrane-spanning ligand-gated Na^+ and Ca^{+2} ion channels and are prominent in all autonomic ganglia and at the neuromuscular end plate; they are blocked by tubocurarine but not atropine. Substances that activate muscarinic and/or nicotinic receptors are referred to as parasympathomimetic, cholinergic, or cholinomimetic. Activation of muscarinic receptors results in miosis, salivation, lacrimation, nausea and vomiting, bradycardia, increased GI motility, micturition, increased bronchial secretions and bronchoconstriction, hypotension, and diaphoresis. Two mnemonics have been developed to help recall muscarinic symptoms: DUMB BELS (**d**iarrhea, **u**rination, **m**iosis, **b**radycardia, and **b**ronchorrhea-**b**ronchoconstriction, **e**mesis, **l**acrimation, **s**weating-salivation)[135] and SLUDGE (**s**alivation, **l**acrimation, **u**rination, **d**efecation, **G**I distress, **e**mesis-eye findings, miosis).[92]

Agents that cause these symptoms include organophosphate and carbamate insecticides (cholinesterase inhibitors),[379] pilocarpine, physostigmine, and certain species of mushrooms that contain muscarine.

Activation of nicotinic receptors initially stimulates postjunctional response but at high dose produces inhibition. Symptoms of activation of nicotinic cholinergic receptors at the neuromuscular junction include muscular twitching, weakness, and paralysis; stimulation of nicotinic receptors at sympathetic ganglia causes hypertension, tachycardia, and mydriasis. Agents that result in symptoms of both muscarinic and nicotinic cholinergic stimulation include organophosphate, carbamate, and nicotine-containing insecticides.

Anticholinergic Induced

Anticholinergic agents produce a syndrome somewhat similar to that associated with stimulation of sympathetic neurons (inhibition of cholinergic response leads to unopposed sympathomimetic activity). These symptoms include agitation, delirium, coma, tachycardia, hypertension, elevated temperature, and mydriasis. Important additional anticholinergic symptoms that distinguish this syndrome from the sympathomimetic syndrome are urinary retention; decreased bowel sounds; dry, flushed skin; and dry mouth. A mnemonic phrase will help the reader remember these symptoms: "red as a beet, dry as a bone, mad as a hatter, hot as stone, bowel and bladder lose their tone, and the heart runs alone."[422] Substances that cause the anticholinergic syndrome include antihistamines, atropine, cyclic antidepressant drugs, phenothiazines, anti-Parkinson's drugs, skeletal muscle relaxants, scopolamine, and several plants that contain so-called belladonna alkaloids (atropine or scopolamine), such as jimsonweed.

Opioid Induced

Another important toxic syndrome is that caused by *opioids.* This toxidrome includes coma, respiratory depression, bradycardia, hypotension, hypothermia, miosis, pulmonary edema, decreased bowel sounds, and decreased reflexes. Common causes of this syndrome, in which CNS depression is a cardinal sign, include morphine, codeine, oxycodone, hydrocodone, hydromorphone, propoxyphene, pentazocine, methadone, and meperidine. The toxidrome caused by *sedative-hypnotic drugs* and *ethanol* is similar to that for the opioids, except that sedative-hypnotic drugs generally produce miosis initially but then in later stages of coma cause mydriasis. Ethanol intoxication typically causes mydriasis. Included in this category of drugs are the benzodiazepines, barbiturates, γ-hydroxybutyrate (GHB),

meprobamate, ethchlorvynol, glutethimide, methaqualone, and ethanol. Some laboratories provide a drug screen panel, variously known as a coma panel, narcotic panel, or sedative-hypnotic panel, designed to detect many drugs that produce these symptoms.

Abstinence Syndromes

Chronic use of certain drugs results in tolerance to some of their pharmacological effects and thus to accelerated doses to achieve desired responses. Abrupt discontinuance of drugs in individuals who have developed tolerance may lead to an abstinence or *withdrawal syndrome*, which tends to be opposite to the original effects produced by the drugs. For example, symptoms of sedative-hypnotic and alcohol withdrawal include dilated pupils, sweating, tachycardia, increased blood pressure, nausea, vomiting, muscle spasm, insomnia, anxiety, irritability, increased temperature, tremor, hallucinations, and seizures. With the exception of seizures and hallucinations, opioid withdrawal shares other features of alcohol or sedative-hypnotic withdrawal. Additional features characteristic of opioid withdrawal include yawning, lacrimation, rhinorrhea, piloerection, diarrhea, and muscle ache. Withdrawal from chronic cocaine use causes dysphoria, somnolence, fatigue, depression, and bradycardia.[333] Elicitation of a withdrawal response is evidence of physical drug dependence. Barbiturate or ethanol withdrawal may be so severe as to be life-threatening. Laboratory confirmation of the nature of the withdrawal syndrome may help initiate proper treatment.

Other toxic syndromes will be discussed in subsequent sections of the chapter.

SCREENING PROCEDURES FOR DETECTION OF DRUGS

Screening procedures are designed for the relatively rapid and generally qualitative detection of drugs or other toxic substances. In general, screening tests have adequate sensitivity but may not be highly specific. Thus a negative result yielded by a screening procedure rules out the presence of clinically significant concentrations of a particular analyte with reasonable certainty. Because of possible interferences, a positive result should be considered "presumptive positive" and should be confirmed by an alternate procedure of greater specificity. Screening procedures may be designed to detect a particular drug or drug class. Tests for such purposes include simple visual color tests (spot tests), determination of serum osmol gap, and immunoassays. Screening procedures capable of detecting a broad range of drugs and metabolites generally involve the use of some type of a separation technique, such as planar chromatography (TLC), GC, or HPLC.

Spot Tests

Spot tests are rapid, easily performed, noninstrumental qualitative procedures that provide presumptive evidence for the presence of tested drugs. Any positive response must be followed by testing with a more specific method. They are valuable to rule out the presence of drugs or to suggest (but not prove) the presence of a drug of a particular group. Spot tests are now less frequently employed, some largely replaced by rapid immunoassays that may be performed at the point-of-care or in the central laboratory.) Methods for the spot test detection of acetaminophen,[49,359,424] salicylate,[424,452] phenothiazines,[160] and ethchlorvynol[193] are found in the Chapter 34 Appendix that is located on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/. A more extensive list of spot tests can be found in a previous edition of this textbook.[53]

Determination of Volatiles by Serum Osmol Gap

The principal osmotically active constituents of serum are Na^+, Cl^-, HCO_3^-, glucose, and urea. Several empirical formulas based on the measurement of these substances have been used to calculate the serum osmolality. One commonly used formula is[174,350]:

$$\text{mOsm/kg} = \left[1.86\,\text{Na}^+\,(\text{mmol/L}) + \frac{\text{glucose (mg/dL)}}{18}\right] + \frac{\text{urea N (mg/dL)}}{2.8} + 0.93$$

The difference between the actual osmolality, measured by freezing-point depression, and the calculated osmolality is referred to as *delta-osmolality*, or the *osmol gap*. Normally, the osmol gap is <10 mOsm/kg. Alcohols, acetone, and ethylene glycol, when present at significant concentrations, increase actual serum osmolality and would thus result in an increased osmol gap (>10 mOsm/kg). Volatile substances are not detected when osmolality is measured with a vapor pressure osmometer. Therefore for the purpose of determining the osmol gap, only osmolality measurements based on freezing-point depression are acceptable. The determination of the osmol gap is a rapid means to detect exogenous, nonionized osmolutes present at milligram-per-deciliter concentrations.

Each 100 mg/dL of ethanol in serum results in a delta-osmolality of 21.7 mOsm/kg.[349] By considering this predictable effect of ethanol on the serum osmolality, it is possible to determine what portion of an increased osmol gap is due to ethanol. A significant residual osmol gap (>10 mOsm/kg) would suggest the possible presence of isopropanol, methanol, acetone, or ethylene glycol. A nomogram that relates serum ethanol concentration and osmol gap is available to assist with this interpretation.[349] Alternatively, the contribution of ethanol to the measured osmolality can be calculated (ethanol, mg/dL÷4.6) and included in the preceding formula for delta osmolality calculation; these calculations may be programmed on a calculator or minicomputer.[348] This information, in conjunction with the presence or absence of metabolic acidosis or serum acetone, can be helpful to the clinician if specific measurements of alco-

TABLE 34-3 Laboratory Findings Characteristic of Ingestion of Alcohols

Alcohol	Osmol Gap	Metabolic Acidosis With Anion Gap	Serum Acetone	Urine Oxalate
Ethanol	+	−	−	−
Methanol	+	+	−	−
Isopropanol	+	−	+	−
Ethylene glycol	+	+	−	+

hols other than ethanol and of ethylene glycol are not available on an emergency basis (Table 34-3). It must be realized that substances administered to patients such as mannitol (osmotic diuretic) and propylene glycol (solvent for diazepam and phenytoin) may increase serum osmolality. Moreover, this screening method is insensitive to low yet clinically significant concentrations of ethylene glycol (<50 mg/dL) and methanol (<30 mg/dL).[349] After ingestion of methanol, some patients may have increased osmol gaps not entirely accounted for by the presence of methanol.[266,306]

Immunoassay

Different types of immunoassay are useful methods to screen specimens for drugs (see Chapters 9 and 33). They include enzyme-multiplied immunoassay technique (EMIT), fluorescence polarization immunoassay (FPIA), cloned enzyme donor immunoassay (CEDIA), kinetic microparticle immunoassay (Abuscreen Online), and radioimmunoassay (RIA). In some cases, these assays are relatively specific for a single drug (e.g., PCP or propoxyphene), but in others, several drugs of a similar class are detected (e.g., opiates, barbiturates, β-phenylethylamines ["amphetamines"]). The detection limit for various members of a class of drugs (e.g., opiates) or the degree of cross-reactivity for similar drugs (e.g., sympathomimetic amines) varies, and each manufacturer of immunoassay reagents should be consulted for specific information. These assays are easy to perform, the results are "semi-quantitative" (higher or lower than a predetermined calibrator cut-off concentration) rather than subjective (e.g., TLC), and they generally have low detection limits (0.02 to 1.0 μg/mL). Several nonisotopic immunoassays (e.g., EMIT, CEDIA, Online, and FPIA) have been automated (see Chapter 11). A number of portable, noninstrumental immunoassay-based drug detection devices are available for nonlaboratory, point-of-care (POC) use (see section On-Site Drug Testing). Test principles for these devices include solid phase enzyme immunoassay, microparticle capture immunochromatography, latex agglutination-inhibition, or gold microparticle capture immunoassay.

For comprehensive clinical (emergency) drug screening, immunoassays complement chromatographic procedures (TLC and GC), because they detect the drugs that would require hydrolysis before chromatography (e.g., morphine-3-glucuronide and oxazepam glucuronide), that may require a separate extraction (e.g., benzoylecgonine), or that have high TLC detection limits (e.g., PCP).

For drug abuse detection, immunoassays are the methods of choice for initial screening (see later section on Drugs of Abuse).

Planar Chromatography

Planar chromatography, commonly known as thin-layer chromatography (TLC), is a versatile procedure that requires no instrumentation and thus is operationally relatively simple and inexpensive (see Chapter 6). However, its application to drug screening requires considerable experience and skill to recognize drug and metabolite patterns and the various detection color hues. With this technique, a large number of drugs may be detected; it may be applied to the analysis of serum, gastric contents, or urine. Urine, however, is the specimen of choice, because most drugs and drug metabolites are present in urine in relatively high concentrations. Although the detection limit varies for each drug and with the conditions of extraction and detection, it is generally on the order of 0.5 to 4.0 μg/mL. Procedures for drug screening using conventional TLC plates have been described.[39,49,67,72,159] Most TLC plates used for drug detection are coated with silica gel. Although these plates may be prepared in the analyst's laboratory, most find it advantageous to purchase commercial precoated plates. After extraction and specimen spotting, the TLC plates are developed with appropriate solvents to achieve chromatographic resolution. The drugs and metabolites are then visualized as spots by their fluorescence or ultraviolet absorbance and by their color development with a combination of reagent sprays or dip solutions. Identification is made by co-chromatographing reference compounds with the unknowns followed by comparison of their relative migration distances (known as R_f values) and detection characteristics with those of the unknowns.

Although some laboratories use a single TLC plate for drug screening, it is advantageous to use as many as three separate plates per urine specimen.[67,72] Different developing solvents may then be used to separate drugs more effectively in the acidic-neutral and the basic drug classes. In addition, the sequential application of multiple spray reagents to a single TLC plate results in diffusion of spots and increases the complexity of interpretation. Some commonly used drug detection reagents and their preparation are:

Ninhydrin. Reacts with drugs that contain primary or secondary amines, such as amphetamine and other sympathomimetic amines. Dissolve 100 mg ninhydrin in 100 mL of acetone. Prepare fresh reagent for each test.

Mercuric sulfate. Forms white precipitate with barbiturates, glutethimide, and phenytoin. Suspend 5 g of mercuric oxide in 100 mL of water. Add, while mixing, 20 mL of concentrated sulfuric acid. Cool and dilute to 250 mL with water. This reagent is stable indefinitely at room temperatures in a closed container.

Diphenylcarbazone. Reacts with barbiturates, glutethimide, and phenytoin to form blue or purple spots. Dissolve 10 mg of diphenylcarbazone in 50:50 chloroform:acetone. Reagent will remain stable for 1 month at room temperature when stored in a brown bottle.

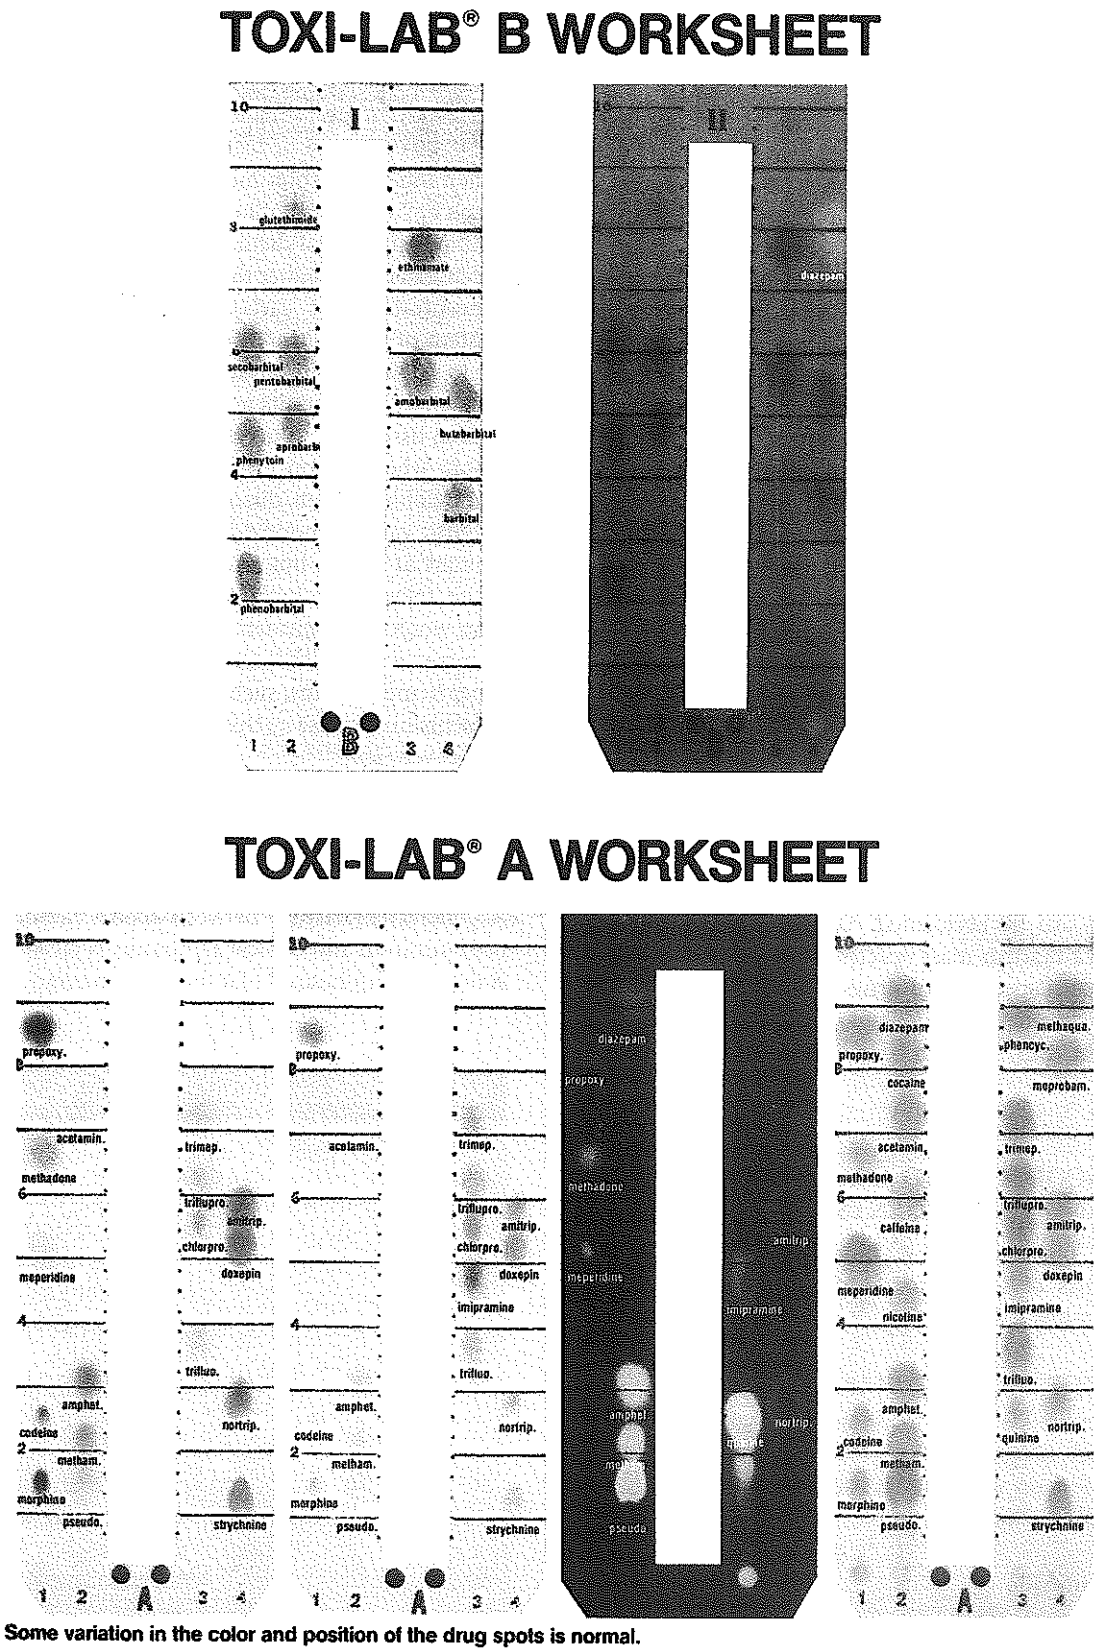
Iodoplatinate. Forms various colors with tertiary amine compounds. Dissolve 1.0 g platinic chloride in about 50 mL of water. Dissolve 10 g of potassium iodide in about 200 mL of water. Add the potassium iodide solution to the platinic chloride solution and dilute to 500 mL with water. Store in a dark bottle. Solution will remain stable for 6 months.

Dragendorff's reagent. Methaqualone forms an orange color; most drugs form a brown color. Dissolve 2.2 g of bismuth subnitrate in 25 mL of glacial acetic acid and add 100 mL of water. Dissolve 50 g of potassium iodide in 125 mL of water. Combine 10 mL of each of these solutions with 20 mL of glacial acetic acid and 100 mL of water. Store in dark bottle. Reagent will remain stable for 6 months.

Absorption of ultraviolet light (254 nm). For determination of benzodiazepines, barbiturates, and methaqualone.

Fluorescence of long ultraviolet light (366 nm). For determination of benzodiazepines, quinine, and quinidine.

The TLC plates most commonly used in clinical toxicology laboratories are designed for convenient and rapid specimen application, solvent migration, and detection. The example presented here is the commercially available Toxi-Lab system manufactured by Varian (Lake Forest, Calif.). The plates are made of glass microfibers impregnated with silicic acid. Specimen application is facilitated by the rapid evaporation of the solvent in the extract in the presence of a glass fiber disk. During evaporation, the specimen is absorbed onto the disk, which is then placed in a prepunched hole on the TLC strip. Thus time-consuming specimen spotting is avoided. Moreover, disks containing reference drugs are already in place on the TLC strips.



Extraction tubes prefilled with buffer salts and solvents are provided. It is necessary only to add ~5 mL of urine and extract by mixing. Acid and neutral drugs are extracted at pH 4.5 and basic-neutral drugs at pH 9.0. Each extract is concentrated onto a specimen application disk.

The chromatographic strip for acidic-neutral drugs contains application disks that have 11 reference drugs already preabsorbed into them (Figure 34-1, *A* and Color Plate 1). After placing the disk containing the absorbed unknown specimen in the precut hole, the strip is developed in chloroform:ethyl acetate (60:40) that contains a trace of ammonium hydroxide. The strips are dried and then dipped into three color development solutions: diphenylcarbazone, silver nitrate, and mercuric sulfate. Barbiturates, phenytoin, glutethimide, and ethinamate appear as blue spots. When observed under long ultraviolet light (366 nm), the barbiturates absorb light (form a dark spot), whereas diazepam fluoresces. Identification is made by direct comparison of the properties of the unknown spots with those of the reference drugs.

The chromatographic strips for basic drugs contain a reference disk that has a total of 26 preabsorbed reference drugs (see Figure 34-1, *B* and Color Plate 1). The disk containing extracted and absorbed drugs from the unknown is placed on the chromatographic strip, which is then developed with methanol:water:ethyl acetate solution (2:1:58) containing a trace of ammonium hydroxide. After drying, the strip is saturated with formaldehyde vapor and then dipped into sulfuric acid. Many basic drugs form a variety of colors. Upon dipping the plate in water, the color for some drugs disappears, some drugs change color, and some drugs form a color for the first time. The plate is then viewed under long ultraviolet light (366 nm), and fluorescent spots are noted. Finally the plate is dipped into a modified Dragendorff's reagent, which produces a brown color for most drugs. The R_f values and color development or fluorescence at each of the four stages are compared for the reference drugs and the unknown(s). Important information on expected metabolite patterns for many drugs is provided by the manufacturer. The entire procedure may be completed in approximately 30 to 40 minutes.

Gas Chromatography

Also known as gas liquid chromatography, GC is relatively rapid, is capable of resolving a broad spectrum of drugs, and is widely used for qualitative and quantitative drug analysis.[150] Capillary columns, because of their high efficiency, have become the most commonly used analytical columns for drug detection by GC (see Chapter 6). In many instances, nonderivatized drugs have good GC properties when capillary columns are used; in some instances, derivatization to a less polar or more volatile compound is necessary. Common detectors for drug detection by GC are flame ionization and alkali flame ionization (nitrogen phosphorus) detectors and mass spectrometers, which provide the greatest accuracy of identification. An automated method for general drug screening by GC-MS spectrometry has been published.[367] A screening method based on GC with flame ionization detection is included in the Chapter 33 Appendix that is found on the book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Some variation in the color and position of the drug spots is normal.

High-Performance Liquid Chromatography

The resolving power of HPLC (see Chapter 6) for separating widely divergent chemical constituents has been applied to the complex challenge of comprehensive drug screening in biological fluids. Advantages of HPLC over GC include the ability to analyze polar compounds without derivatization (e.g., morphine and benzoylecgonine) and thermally labile drugs (e.g., chlordiazepoxide). In 1991 a chromatographic retention time database for drugs became available.[59] Moreover the advent of detectors that can provide a spectral scan of compounds as they elute from the column has greatly increased the discriminatory power of this technique. Screening procedures for 225 to 370 drugs have been reported that use gradient elution with reverse-phase columns and spectral scanning with diode-array detectors.[59,290,455] An isocratic, HPLC system with diode-array spectral scanning has been reported for the detection and quantitation of about 30 basic drugs and/or metabolites in serum.[377]

A commercial, completely automated HPLC system designed for drug screening is available (REMEDi; Bio-Rad Laboratories, Hercules, Calif.) and has been evaluated in a general hospital setting.[389] This system uses four columns in series and column switching techniques to extract, separate, and perform a spectral scan on eluted drugs. Identification of about 300 drugs and metabolites is based on computer matching of retention time and spectra with comparable data stored in the drug library. Quantitation of identified drugs may also be performed. This device has also been adapted to a tandem mass spectrometry for the identification of a broad spectrum of drugs in urine.[153]

Liquid chromatography-single quadruple mass spectrometry (LC-MS) has also been applied to drug screening in serum.[442,460]

PHARMACOLOGY AND ANALYSIS OF SPECIFIC DRUGS AND TOXIC AGENTS

The toxic, pharmacological, biochemical, and analytical characteristics of several individual drugs and toxins are discussed in this section.

Agents That Cause Cellular Hypoxia

Carbon monoxide and methemoglobin-forming agents interfere with oxygen transport, resulting in cellular hypoxia. Cyanide interferes with oxygen use and therefore causes an apparent cellular hypoxia.

Carbon Monoxide

Carbon monoxide (CO) is a colorless, odorless, tasteless gas that is a product of incomplete combustion of carbonaceous material. Common exogenous sources of carbon monoxide include cigarette smoke, gasoline engines, and improperly ventilated home heating units. Small amounts of carbon monoxide are produced endogenously in the metabolic conversion of heme to biliverdin.[264] This endogenous production of carbon monoxide is accelerated in hemolytic anemias.[287]

Toxic Effects

When inhaled, carbon monoxide combines tightly with the heme Fe^{2+} of hemoglobin to form carboxyhemoglobin. The binding affinity of hemoglobin for carbon monoxide is about 250 times greater than that for oxygen. Therefore high concentrations of carboxyhemoglobin limit the oxygen content of blood. Moreover, the binding of carbon monoxide to a hemoglobin subunit increases the oxygen affinity for the remaining subunits in the hemoglobin tetramer. Thus at a given tissue PO_2 value, less oxygen dissociates from hemoglobin when carbon monoxide is also bound, shifting the hemoglobin-oxygen dissociation curve to the left. Consequently, carbon monoxide not only decreases the oxygen content of blood, but also decreases oxygen availability to tissue, thereby producing a greater degree of tissue hypoxia than would an equivalent reduction in oxyhemoglobin due to hypoxia alone.[216,446] Carbon monoxide may also bind to other heme proteins, such as myoglobin and mitochondrial cytochrome oxidase a_3; this may limit oxygen use when tissue PO_2 is very low.[171,216]

The toxic effects of carbon monoxide are a result of hypoxia. Organs with high oxygen demand, such as the heart and brain, are most sensitive to hypoxia and thus account for the major clinical sequelae of carbon monoxide poisoning. A general correlation between blood carboxyhemoglobin concentration and clinical symptoms is given in Table 34-4. It must be emphasized that the carboxyhemoglobin concen-

TABLE 34-4 Carboxyhemoglobin Effects

Carboxyhemoglobin (%)	Response
10	Shortness of breath on vigorous muscular exertion
20	Shortness of breath on moderate exertion, slight headache
30	Decided headache, irritation, ready fatigue, and disturbance of judgment
40-50	Headache, confusion, collapse, and fainting on exertion
60-70	Unconsciousness, respiratory failure, and death if exposure is continued
80	Rapidly fatal
Over 80	Immediately fatal

From Deichmann WB, Gerarde HW. Symptomatology and therapy of toxicological emergencies. New York: Academic Press Inc, 1964.

tration, although helpful in diagnosis, does not always correlate with the clinical findings or prognosis.[324,392] Factors other than carboxyhemoglobin concentration that contribute to the toxicity include length of exposure, metabolic activity, and underlying disease, especially cardiac or cerebrovascular disease. Moreover, low carboxyhemoglobin concentrations relative to the severity of poisoning may be observed if the patient was removed from the carbon monoxide–contaminated environment several hours before blood sampling.

One of the more insidious effects of carbon monoxide poisoning is the delayed development of neuropsychiatric sequelae, which may include personality changes, motor disturbances, and memory impairment. These manifestations do not correlate either with the length of exposure or the maximum blood carboxyhemoglobin concentration but are more likely if patients experienced a deep coma.[25]

Treatment for carbon monoxide poisoning involves removal of the individual from the contaminated area and the administration of oxygen. The half-life of carboxyhemoglobin is 5 to 6 hours when the patient breathes room air; it is reduced to about 1.5 hours when he or she breathes 100% oxygen. In severe cases, hyperbaric oxygen treatment at 2 to 3 atmospheres is recommended, if available. In the latter instance, the carboxyhemoglobin half-life is reduced to about 25 minutes.[446] Hyperbaric oxygen therapy may reduce the incidence of neurological manifestations after exposure.[300] Hyperbaric oxygen therapy has been recommended when the carboxyhemoglobin concentration exceeds 25%.[178] It has been suggested that decisions should not be made to institute hyperbaric oxygenation based solely on the carboxyhemoglobin concentration owing to the inconsistent correlation between such a measurement and clinical severity.[300,324] However, this therapy is recommended for any patient with loss of consciousness, significant neurological symptoms, cardiovascular complications, or severe acidosis regardless of the carboxyhemoglobin concentration.[212]

Analytical Methodology

Carbon monoxide may be released from hemoglobin and then measured by GC, or it may be determined indirectly as carboxyhemoglobin by spectrophotometry. Gas chromatographic methods are accurate and precise even for very low concentrations of carbon monoxide. The spectrophotometric methods are rapid, convenient, accurate, and precise, except at very low concentrations of carboxyhemoglobin (<2% to 3%).

Gas chromatographic methods measure the carbon monoxide content of blood. When blood is treated with potassium ferricyanide, carboxyhemoglobin is converted to methemoglobin, and the carbon monoxide is released into the gas phase. Measurement of the released carbon monoxide may be performed by GC using a molecular sieve column and a thermal conductivity detector.[124] A lower detection limit is achieved by incorporating a reducing catalyst (e.g., nickel) between the GC column and the detector to convert carbon monoxide to methane. The methane may then be detected with a flame ionization detector.[182] A very low detection limit may also be achieved by the use of a heated mercuric oxide reaction chamber between the GC column and an ultraviolet light detector. As carbon monoxide elutes from the column, it reacts with mercuric oxide to form mercury gas, which has a high molar absorptivity at 254 nm.[463] In practice, the carbon monoxide binding capacity is also determined after an aliquot of the blood specimen is treated with carbon monoxide to saturate the hemoglobin. The results are then expressed as percent of carboxyhemoglobin:

$$\%\,\mathrm{HbCO} = \frac{\mathrm{CO\ content}}{\mathrm{CO\ capacity}} \times 100$$

GC methods are accurate and precise and are considered to be reference procedures. Normal values for carboxyhemoglobin in rural nonsmokers are about 0.5%; for urban nonsmokers, 1% to 2%; and for smokers, 5% to 6%.[27] Values may be increased by about 3% in hemolytic anemias.[287]

Spectrophotometric methods rely on the characteristic spectral absorption properties of carboxyhemoglobin.[501] Of several such methods, the most popular are based on automated, multiwavelength measurements of several hemoglobin species. Commercially available instruments (Instrumentation Laboratories' Co-Oximeter [Lexington, Mass.], Radiometer's OSM 3 Hemoximeter [Copenhagen, Denmark], Bayer Diagnostics Co-Oximeter [Tarrytown, N.Y.], and Roche Diagnostic's AVL Co-Oxylite [Indianapolis]) perform absorption measurements on blood specimens at 4 to 7 wavelengths and then compute the concentration of deoxyhemoglobin, oxyhemoglobin, carboxyhemoglobin, and methemoglobin based on a series of matrix coefficients. A more advanced optical system is based on a 128-wavelength spectrometer (ABL 700; Radiometer, Copenhagen, Denmark).

The spectrophotometric methods generally compare favorably with gas chromatographic procedures at carboxyhemoglobin concentrations greater than 2% to 3%, but their precision is poor below these levels.[463] Therefore, they are sufficiently accurate and precise for measurement of carbon monoxide after exogenous exposure but are too insensitive to detect the increased endogenous production of carbon monoxide that occurs in hemolytic anemias.

Fetal hemoglobin has slightly different spectral properties than adult hemoglobin. Consequently, falsely high carboxyhemoglobin values of 4% to 7% may occur when blood from neonates is measured by some spectrophotometric methods.[464] Moreover, erroneous results may occur with lipemic specimens and in the presence of methylene blue (see section on Methemoglobin-Forming Agents). These interferences are eliminated or greatly minimized by Radiometer's ABL 700.

The automated, multicomponent spectrophotometric methods for the determination of carboxyhemoglobin and

other hemoglobin species are the most rapid and convenient. A spectrophotometric procedure for carboxyhemoglobin[444] applicable to manual spectrophotometers is included in the the Chapter 34 Appendix that is found on the book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). This procedure provides results that are in agreement with those of a gas chromatographic[334] and of an automated, multiwavelength spectrophotometric method.[202]

Cyanide

Hydrocyanic acid, often referred to as *prussic acid* or as *cyanide* when in the ionized state (CN^-), is a colorless, odorless gas released when anything containing ionically bound or complexed CN^- is exposed to acid. Burning of urea foam produces formaldehyde and hydrocyanic acid; fires in homes with urea foam insulation represent a significant source of exposure.

Toxic Effects

When inhaled, hydrocyanic acid is rapidly absorbed across alveolar capillaries into blood where it binds to hemoglobin. The hydrocyanic acid bound in the erythrocyte is in equilibrium with free hydrocyanic acid in the serum at a ratio of 10:1. Cyanide in serum readily crosses all biological membranes and avidly binds to heme iron (Fe^{3+}) in the cytochrome a-a_3 complex within mitochondria.[398,462] When bound to cytochrome a-a_3, CN^- is a competitive inhibitor and causes uncoupling of oxidative phosphorylation. Patients exposed to toxic levels of cyanide exhibit rapid onset of symptoms typical of cellular hypoxia—flushing, headache, tachypnea, dizziness, and respiratory depression—which progress rapidly to coma, seizure, complete heart block, and death if the dose is sufficiently large. Symptoms are usually dose related and correlate strongly with CN^- concentration.[9] Treatment requires rapid identification of CN^- as the intoxicant followed by administration of sodium nitrite to cause formation of methemoglobin, which avidly binds and clears CN^-, and thiosulfate (a sulfur donor) to enhance clearance via metabolism.

Cyanide is metabolized by the ubiquitous enzyme rhodanase to thiocyanate (SCN^-), drawing on the body's sulfur-donor pool for substrate to convert CN^- to SCN^-. Thiocyanate is relatively inert and is cleared by the kidney. The conversion of CN^- to SCN^- occurs slowly relative to the pharmacological action of CN^-, so measurement of SCN^- is of use in monitoring clearance but not very useful in assessing acute CN^- exposure. In an acute exposure, the patient experiences symptoms of toxicity with high blood CN^- levels, but the serum SCN^- level remains low until 12 to 24 hours later.[9,312]

Administration of nitroprusside to control acute hypertension contributes to the total body pool of CN^- and complicates the interpretation of the blood CN^- concentration. Nitroprusside ($Fe[CN]_5NO$) avidly binds to hemoglobin in erythrocytes; at equilibrium, the amount of CN^- that is bound in the erythrocyte owing to nitroprusside as compared with that of the serum is 200:1, approximately 20 times that found in the erythrocyte if the exposure were due to ionic CN^-. These patients do not exhibit CN^- toxicity unless they are unable to clear the drug. Measurement of SCN^- is the recommended procedure to monitor nitroprusside therapy, because measurement of blood CN^- will be confounded by all the nitroprusside in the erythrocyte.

The normal CN^- concentration is less than 0.2 μg/mL of whole blood because of the presence of CN^- in foods such as dark green vegetables and nuts that contain cyanogenic glycosides (e.g., amygdalin), and the use of tobacco products that contain CN^-. Normal SCN^- concentration in serum is less than 4 μg/mL, but smokers may have serum SCN^- levels as high as 10 μg/mL. Patients with acute exposure are likely to have high blood CN^- levels and low serum SCN^- concentrations. The patient likely becomes comatose when blood CN^- level is greater than 2 μg/mL, and levels greater than 5 μg/mL are lethal. Patients receiving nitroprusside therapy, however, may have blood CN^- concentrations as high as 50 to 100 μg/mL without symptoms of toxicity.[12]

Analytical Methodology

Following microdiffusion, whole blood CN^- is measured by photometric analysis[10,112] or by ion-selective electrode analysis.

A spectrophotometric procedure for measuring cyanide is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).[10] In this method, a sealed, two-well microdiffusion cell is used to separate hydrocyanic acid from blood by mixing a sample of whole blood with strong acid in a sealed chamber and allowing the hydrocyanic acid gas generated to be absorbed into a strong base located in another part of the sealed chamber. One well of the cell contains the blood specimen and strong acid (unmixed until the cell is sealed), and the other well contains a strong base to absorb the hydrocyanic acid gas. After the hydrocyanic acid is collected in the aqueous base medium, pyridine, barbituric acid, and chloramine-T are added to generate a red complex, with the intensity of the color proportional to the concentration of CN^-. A good-quality spectrophotometer is required to measure the absorbance. Quick and easy methods for serum SCN^- analysis have been described.[461]

Methemoglobin-Forming Agents

The heme iron in hemoglobin is normally in the ferrous state (Fe^{2+}). When oxidized to the ferric state (Fe^{3+}), methemoglobin is formed, and this form of hemoglobin cannot bind oxygen. The principal physiological system to maintain hemoglobin iron in the reduced state is NADH-methemoglobin reductase (diaphorase I) (Figure 34-2). The NADH for this enzyme is supplied by normal glycolysis (Embden-Meyerhof pathway). A minor pathway for methemoglobin reduction involves NADPH-methemoglobin reductase (diaphorase II), and the NADP for this enzyme reaction is derived from the hexose-monophosphate shunt. Congenital

methemoglobinemia may result from a deficiency of NADH–methemoglobin reductase or more rarely from hemoglobin variants (hemoglobin M) in which heme iron is both more susceptible to oxidation and more resistant to reduction by the methemoglobin reductase system.

Toxic Effects

An acquired (toxic) methemoglobinemia may be caused by a number of drugs and chemicals (Table 34-5).

The normal concentration of methemoglobin is <1.5% of total hemoglobin. In otherwise healthy individuals, methemoglobin levels up to 20% cause only cyanosis. Concentrations between 20% and 50% may cause dyspnea, exercise intolerance, fatigue, weakness, and syncope. More severe symptoms of dysrhythmias, seizures, metabolic acidosis, and coma are associated with methemoglobin concentrations of 50% to 70%, and levels >70% may be lethal.[376] All of these symptoms are a consequence of hypoxia associated with the diminished O_2 content of the blood and with a decreased O_2 dissociation from hemoglobin species in which some, but not all, subunits contain heme iron in the ferric state (i.e., shift of dissociation curve to the left). The PO_2 is normal in these patients and therefore so is the calculated hemoglobin oxygen saturation. Thus, a normal PO_2 in a cyanotic patient is a significant indication for the possible presence of methemoglobinemia. The direct measurement of methemoglobin is important in these cases and may be performed by the manual spectrophotometric method of Evelyn and Malloy or by automated multiwavelength measurements with a co-oximeter (see section on Carbon Monoxide).

Specific therapy for toxic methemoglobinemia involves the administration of methylene blue, which acts as an electron transfer agent in the NADPH–methemoglobin reductase reaction and thereby increases the activity of this system several fold (Figure 34-3).[376] Methylene blue and sulfhemoglobin cause spectral interference in the measurement of methemoglobin with some co-oximeters[240,499] but not with the Evelyn-Malloy method.[240]

Analytical Methodology

Methemoglobin is measured manually[240] or by automated multiwavelength measurements with a co-oximeter. As methemoglobin is not stable at room temperature, specimens should be kept on ice or refrigerated but not frozen.[240] The stability of methemoglobin at 4 °C has not been well studied. Some sources indicate significant decreases in methemoglobin concentrations after 4 to 8 hours,[269] whereas others report little or no change after 24 hours.[240] Freezing results in an increase in methemoglobin concentration.[240]

ALCOHOLS

Several alcohols are toxic and medically important. They include ethanol, methanol, and isopropanol.

Alcohols of Toxicological Interest

Ethanol is a widely used and often abused chemical substance. Consequently the measurement of ethanol is one of the more frequently performed tests in the toxicology laboratory. Although less frequently encountered, it is important to include methanol, isopropanol, and acetone (a metabolite of isopropanol) in a test battery for alcohols for proper evaluation of the acutely intoxicated patient.

Ethanol

The principal pharmacological action of ethanol is CNS depression. The CNS effects vary, depending on the blood ethanol concentration, from euphoria and decreased inhibitions (≤50 mg/dL) to increased disorientation and incoordination (100 to 300 mg/dL) and then to coma and death (>400 mg/dL) (Table 34-6). A blood alcohol concentration of 100 mg/dL was previously established as the statutory limit for operation of a motor vehicle in most states in the United States. A new federal mandate requires that this limit be lowered to 80 mg/dL by 2004. Not all individuals experience the same degree of CNS dysfunction at similar blood alcohol levels. Moreover, the CNS actions of ethanol are more pronounced when the blood ethanol concentration is increasing (absorptive phase) than when it is declining (elimination phase), partly because of the phenomenon of acute tolerance.[176] In addition, heavy alcohol use leads to a more chronic form of tolerance. When consumed with other CNS depressant drugs, ethanol exerts a potentiation or synergistic depressant effect. This can occur at relatively low alcohol concentrations, and a number of deaths have resulted from combined ethanol and drug ingestion.[168]

The pharmacological mechanisms for the CNS depressant actions of ethanol are complex and incompletely understood, but probably involve both enhancement of major inhibitory neurons and impairment of excitatory neurons. The principal CNS inhibitory neuronal system is mediated by the neurotransmitter γ-aminobutyric acid (GABA). When GABA binds to its postsynaptic receptor subtype $GABA_A$, this oligomeric ion-gated complex "opens" to allow inward flux of Cl^-, leading to membrane hyperpolarization and subsequent decreased electrical response. This GABA-mediated inhibitory response is enhanced by ethanol and other CNS depressant drugs, such as barbiturates, benzodiazepines, and most general anesthetic agents. A major CNS excitatory response is mediated by the neurotransmitter glutamate. Ethanol inhibits the excitatory response mediated by a Ca^{2+} ion-gated glutamate receptor subtype termed the *N*-methyl-D-aspartate (NMDA) receptor. Additionally, central adrenergic stimulation may be indirectly inhibited by ethanol via its enhancement of the activity of phenylethanolamine-*N*-methyltransferase (PNMT), the enzyme responsible for the extraneuronal conversion of norepinephrine to epinephrine. Epinephrine in turn activates presynaptic α_2-receptors, which inhibit the release of norepinephrine. The aforementioned chronic tolerance to ethanol is considered to be mediated by ethanol-induced increased responsiveness and upregulation in the synthesis of NMDA receptors, by a concomitant downregulation and desensitization of $GABA_A$ receptors, and by downregulation of the presynatic α_2-adrenergic receptors. Largely because of these adaptive changes, abrupt withdrawal from chronic, heavy ethanol use leads to a physical abstinence syndrome, which has prominent features of CNS excitation. Included among these withdrawal symptoms are anxiety, irritability, insomnia, muscle tremor and cramps, seizures, hallucinations, and increased temperature, blood pressure, and heart rate.

Ethanol is metabolized principally by liver alcohol dehydrogenase to acetaldehyde, which is subsequently oxidized to acetic acid by aldehyde dehydrogenase. The rate of elimination of ethanol from blood generally approximates a zero-order process. Although this rate varies among individuals, it averages about 15 mg/dL/h (ranging from 11 to 22 mg/dL/h) for males and 18 mg/dL/h (ranging from 11 to 22 mg/dL/h) for females.[125] At both low (<20 mg/dL)[465] and high (>300 mg/dL) ethanol concentrations, the elimination becomes more nearly first-order and is accelerated at high concentrations (e.g., ~22 mg/dL/h at ~300 mg/dL).[58] The elimination rate is also influenced by drinking practice (e.g., alcoholics have average elimination rates of about 30 mg/dL/h).[480]

Ethanol is a teratogen, and alcohol consumption during pregnancy can result in the baby being born with fetal alcohol spectrum disorders (FASD). FASD is an umbrella term describing the range of effects that can occur in an individual whose mother drank alcohol during pregnancy (http://www.nofas.org). These effects may include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications. The term FASD is not intended for use as a clinical diagnosis. Other alcohol-related conditions include alcohol-related neurodevelopmental disorder (ARND) and alcohol-related birth defects (ARBD). As many as 12,000 infants are born each year with FAS, and three times as many have ARND or ARBD. FAS, ARND, and ARBD affect more newborns every year than Down syndrome, cystic fibrosis, spina bifida, and sudden infant death syndrome combined (http://www.nofas.org). FAS, ARND,

TABLE 34-6 Stages of Acute Alcoholic Influence/Intoxication

Blood Alcohol Concentration (g/100 mL)	Stage of Alcoholic Influence	Clinical Signs/Symptoms
0.01-0.05	Subclinical	Influence/effects not apparent or obvious Behavior nearly normal by ordinary observation Impairment detectable by special tests
0.03-0.12	Euphoria	Mild euphoria, sociability, talkativeness Increased self-confidence; decreased inhibitions Diminution of attention, judgment, and control Some sensory-motor impairment Slowed information processing Loss of efficiency in finer performance tests
0.09-0.25	Excitement	Emotional instability; loss of critical judgment Impairment of perception, memory, and comprehension Decreased sensory response; increased reaction time Reduced visual acuity, peripheral vision, and glare recovery Sensory-motor incoordination; impaired balance Drowsiness
0.18-0.30	Confusion	Disorientation, mental confusion; dizziness Exaggerated emotional states (fear, rage, grief, etc.) Disturbances of vision (diplopia, etc.) and of perception of color, form, motion, dimensions Increased pain threshold Increased muscular incoordination; staggering gait; slurred speech Apathy, lethargy
0.25-0.40	Stupor	General inertia; approaching loss of motor functions Markedly decreased response to stimuli Marked muscular incoordination; inability to stand or walk Vomiting; incontinence of urine and feces Impaired consciousness; sleep or stupor
0.35-0.50	Coma	Complete unconsciousness; coma; anesthesia Depressed or abolished reflexes Subnormal temperature Impairment of circulation and respiration Possible death
0.45+	Death	Death from respiratory arrest

and ARBD are 100% preventable when a woman completely abstains from alcohol during her pregnancy.

Methanol

Methanol is used as a solvent in a number of commercial products, as a constituent of antifreeze and window cleaning fluids, and as a component of canned fuel. It may be consumed by alcoholics intentionally as an ethanol substitute or accidentally when present as a contaminant in illegal whiskey. Accidental ingestions have occurred in children.

The CNS effects of methanol are substantially less severe than those of ethanol. Methanol is oxidized by liver alcohol dehydrogenase (at about one tenth the rate of ethanol) to formaldehyde. Formaldehyde in turn is rapidly oxidized by aldehyde dehydrogenase to formic acid, which may cause serious acidosis and optic neuropathy, resulting in blindness or death.[296,298] Serum formate concentrations correlate better with the degree of acidosis and the severity of CNS and ocular toxicity than do serum methanol concentrations.[410] Therefore some investigators recommend the measurement

of serum formate to assess the severity of toxicity and to guide appropriate therapy in cases of methanol ingestion. Treatment for methanol intoxication may include the administration of ethanol or preferably fomepizole to inhibit the metabolism of methanol, sodium bicarbonate therapy to help alleviate the metabolic acidosis, folate administration to enhance folate-mediated metabolism of formate, and the use of hemodialysis to enhance clearance of methanol and formate.[22]

Headspace gas chromatographic analysis is the method of choice for the measurement of methanol. An adaptation of this technique may be used to measure formate, the toxic metabolite of methanol, after esterification to methyl formate. These methods are included in the Chapter 34 Appendix that is found on the book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). An enzymatic assay based on formate dehydrogenase has also been reported.[54]

Isopropanol

Isopropanol is readily available to the general population as a 70% aqueous solution for use as rubbing alcohol. It has about twice the CNS depressant action as ethanol, but it is not as toxic as methanol.

Isopropanol has a short half-life ($t_{1/2}$) of 1 to 6 hours, as it is rapidly metabolized by alcohol dehydrogenase to acetone, which is eliminated much more slowly ($t_{1/2}$, 17 to 27 hours), primarily in alveolar air and urine.[115,228,313,326] Therefore concentrations of acetone in serum often exceed those of isopropanol during the elimination phase following isopropanol ingestion (Figure 34-4). Acetone has CNS depressant activity similar to that of ethanol, and because of its longer half-life, it prolongs the apparent CNS effects of isopropanol.

Severe isopropanol intoxication, like that of ethanol, can result in coma or death. Appropriate therapy in such cases includes hemodialysis. The therapeutic administration of ethanol is not indicated for isopropanol intoxication.

Isopropanol and its metabolite, acetone, may be determined by headspace gas chromatography or by NMR spectroscopy.[313] A headspace gas chromatographic method is included in the Chapter 34 Appendix that is found on the book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Analysis of Alcohols*

Similar techniques are used to measure alcohol in blood, serum, saliva, or urine and for postmortem specimens (e.g. vitreous fluid and skeletal muscle). Determination of ethanol in expired air requires specialized breath alcohol analyzers (see section on Breath Alcohol).

*In this section, the term "alcohol" is defined as ethanol unless otherwise indicated.

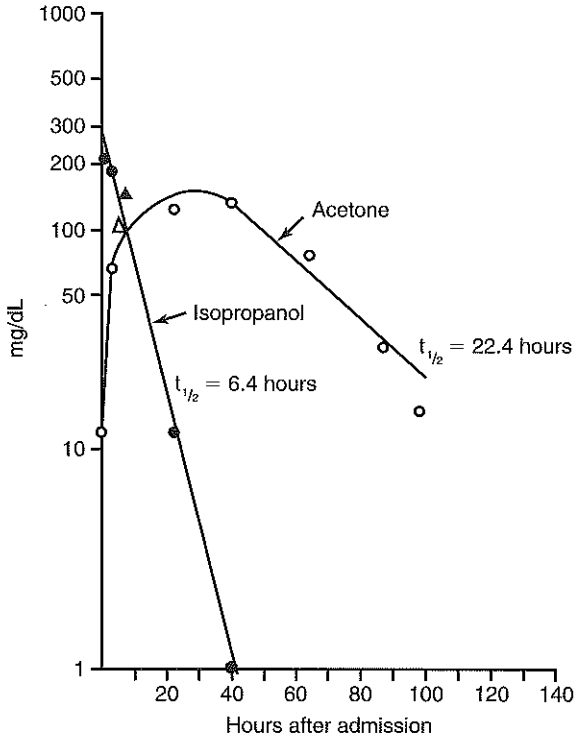

Figure 34-4 Isopropanol and acetone concentrations in serum after an acute overdose of isopropanol. Closed and open circles indicate serum isopropanol and acetone concentrations, respectively. Isopropanol and acetone concentrations in spinal fluid are indicated by closed and open triangles, respectively. *(From Natowicz M, Donahue J, Gorman L, Kane M, McKissick J, Shaw L. Pharmacokinetic analysis of a case report of isopropanol intoxication. Clin Chem 1985; 31:326-8.)*

Blood Alcohol

Suitable blood-related specimens for the determination of alcohols are serum, plasma, or whole blood. The venipuncture site should be cleansed with an alcohol-free disinfectant, such as aqueous benzalkonium chloride (Zephiran).

Alcohol distributes into the aqueous compartments of blood, and because the water content of serum (~98%) is greater than that of whole blood (~86%), results indicating higher alcohol levels are obtained with serum. Experimentally the serum:whole blood ethanol ratio is 1.14 (1.09 to 1.18) and varies slightly with hematocrit.[479] Several states have enacted laws that define intoxication while driving a motor vehicle under the influence of alcohol based on whole blood ethanol concentrations. Some states do not specify the specimen type. Therefore laboratories that perform alcohol determinations should make clear the choice of specimen.

Because of the volatile nature of alcohols, specimens must be kept capped to avoid evaporative loss to the atmosphere. Blood may be stored, when properly sealed, for 14 days at room temperature or at 4 °C, with or without preservative.[481] For longer storage or for nonsterile postmortem specimens,

sodium fluoride should be used as a preservative to prevent a decrease or occasionally an increase (via fermentation) in ethanol concentration.

To measure ethanol in blood, enzymatic analysis is the method of choice for many laboratories. In this method, ethanol is measured by oxidation to acetaldehyde with NAD^+, a reaction catalyzed by alcohol dehydrogenase (ADH). With this reaction, formation of NADH, measured at 340 nm, is proportional to the amount of ethanol in the specimen. The reaction is driven almost completely to the right by use of excess NAD^+ and ADH and agents such as semicarbazide or tris (hydroxymethyl) aminomethane to trap acetaldehyde as it is formed.[165]

Under most assay conditions, ADH is reasonably specific for ethanol. Interference, relative to ethanol, is generally about 7% for isopropanol, 3% for methanol, and 4% for ethylene glycol.[165] Reagent kits for use with manual spectrophotometers or automated analyzers are available from several manufacturers. Some manufacturers (Dade-Behring [*aca*], Abbott [TDx], Dade-Behring [EMIT]) claim interference from isopropanol, methanol, acetone, and ethylene glycol to be less than 1%.

Serum (or plasma) is the most common specimen for ethanol analysis by ADH methods; the method also performs well with urine or saliva. In some methods, whole blood may be used directly,[77] but in others, a precipitation step may be required before analysis to avoid interference from hemoglobin.[166] These methods generally compare closely with gas chromatographic methods.[77,176]

Ethanol assays using ADH, especially those that are fully automated, are convenient for clinical laboratories that do not have gas chromatographic instrumentation. The specificity for ethanol must be clearly communicated to physicians treating acutely intoxicated patients. Otherwise, very low or negative ethanol values might be misinterpreted as "alcohol" in a patient who ingested methanol or isopropanol. Ethanol measurements may be used in conjunction with the osmol gap to screen for possible presence of significant quantities of methanol, isopropanol, or ethylene glycol (see Determination of Volatiles by Serum Osmol Gap). A head space gas chromatographic method for alcohols (acetone) is included in the Chapter 34 Appendix that is found on the book's Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Breath Alcohol

Statutory laws for driving under the influence of alcohol were originally based on the concentration of ethanol in venous whole blood. Because the collection of blood is invasive and requires intervention by medical personnel, the determination of alcohol in expired air has long been the mainstay of evidential alcohol measurements.[188,229,299] There is also growing clinical interest in the determination of breath alcohol at the point-of-care. The fundamental principle for use of breath analysis is that alcohol in capillary alveolar blood rapidly equilibrates with alveolar air in a ratio of approximately 2100:1 (blood:breath). Therefore breath alcohol expressed as g/210 L is approximately equivalent to g/dL of alcohol in whole blood. This blood-breath ratio may actually be closer to 2300:1 but in any case is variable. Nevertheless, in the United States evidential breath alcohol measurements are based on the ratio of 2100:1. The lower blood-breath ratio will predict a slightly lower than actual blood alcohol concentration and its use therefore is not prejudicial. To alleviate the confusion and uncertainty surrounding the conversion from breath to blood alcohol concentration, the traffic laws in the United States have been amended to read "alcohol concentration shall mean either grams of alcohol per 100 milliliters of blood or grams per 210 liters of breath."[299] Before breath analysis, a waiting period of 15 minutes is required to allow for clearance of any residual alcohol that may have been present in the mouth (e.g., very recent drinking, the use of alcohol-containing mouthwash, or vomiting alcohol-rich gastric fluid).

During the period of active alcohol absorption (30 to 120 minutes before peak venous blood alcohol concentration), the alcohol concentration in arterial blood may be higher than that in peripheral venous blood.[75] Consequently, breath alcohol concentration may also be higher than that in venous blood during this absorption phase, because end-expiratory air equilibrates with pulmonary arterial blood. The potential consequences of performing breath alcohol analysis during the absorption phase have been the subject of considerable debate.[227,230]

In the interest of public safety, the U.S. Department of Transportation (DOT) has mandated breath alcohol testing in addition to screening for drugs of abuse in urine (see section on Drugs of Abuse) for commercial transportation employees.[450,451] If the breath alcohol concentration is between 0.02 and 0.04 g/210 L for duplicate measurements (within 30 minutes), an employee is not allowed to resume safety-sensitive duties for 8 hours (24 hours for motor vehicle drivers). If the concentration is 0.04 g/210 L or greater, the employee is suspended from duty until evaluation by substance abuse professionals has been obtained and appropriate follow-up testing has been initiated.

Several commercial evidential breath alcohol measurement devices are available. The principle of measurement is either infrared absorption spectrometry (most common), dichromate-sulfuric acid oxidation-reduction (photometric), GC (flame ionization or thermal conductivity detection), electrochemical oxidation (fuel cell), or metal-oxide semiconductor sensors.[188,229] A list has been published of DOT-approved breath alcohol devices.[123,451] Some of these devices are approved for screening only. In this case, the second or "confirmatory" breath alcohol determination must be performed with an approved evidential breath alcohol analyzer. Breath alcohol devices may also be used for the medical evaluation of patients at the point of care (e.g., emergency department). A Fourier transform infrared point-of-care breath analyzer capable of measurement of

ethanol, methanol, and isopropanol performed well in the evaluation and management of patients with methanol poisoning.[260]

Saliva Alcohol

Because saliva (increasingly referred to as oral fluid) may be easily and noninvasively collected, there is growing interest in its use for ethanol measurements and for the detection of drugs of abuse (see Drugs of Abuse). Ethanol distributes between blood and saliva by passive diffusion largely according to the water content of these fluids (85% w/v for whole blood; 99% for saliva).[233] Experimentally the ethanol concentration in saliva is about 9% higher than in whole blood,[233] a value slightly lower than predicted based on their respective water content; the ethanol concentration in serum and saliva would be predicted to be about the same based on their similar water content. The concentration time profiles for ethanol in blood, breath, and saliva are all similar.[232,233]

A small test device, Q.E.D. Saliva Alcohol Test (OraSure Technologies, Bethlehem, Pa.), has been developed to measure ethanol in saliva. Saliva is absorbed onto a swab, which is then inserted into the test cartridge. Ethanol measurement is based on an ADH reaction coupled with a diaphorase-mediated color indicator reaction, which provides for visual end-point detection on a thermometer-like scale after a 2-minute incubation.

This device was evaluated and determined to provide results in agreement with those for breath or venous blood ethanol.[232] The Q.E.D. is suited for on-site use in the emergency department, in the workplace, and potentially at the roadside. It is approved by the DOT for alcohol screening.[449] Although designed for measurement of alcohol in saliva, the Q.E.D. provides accurate measurements for serum ethanol as well.[117]

The ON-SITE alcohol test card device (Roche Diagnostic Systems, Branchburg, N.J.), for the qualitative measurement of ethanol in saliva or urine is also based on an ADH-diaphorase coupled detection scheme. This test card is designed to produce a positive response for ethanol concentrations greater than 0.02 g/dL. This device is also approved by the DOT for screening.[449]

A third DOT-approved device (Alco-Screen 02, Chematics, Inc., North Webster, Ind.) consists of a plastic test strip suitable for insertion under the subject's tongue or into collected saliva. After saturation of the reaction pad with saliva and a 2-minute incubation period, an ADH-diaphorase coupled indicator color bar becomes visible if the ethanol concentration is 0.02 g/dL or greater.

The flow of saliva is largely under the control of the parasympathetic nervous system. Collection of saliva may therefore be difficult from individuals who experience anticholinergic symptomatology (e.g., dry mouth associated with tricyclic antidepressant overdose). In addition, salivary flow may be impaired in some alcoholics.[129]

Urine Alcohol

Urine has been used as an alternate, less invasive specimen for the determination of alcohol, compared with blood. During the postabsorptive phase following alcohol ingestion, the concentration of alcohol in urine is roughly 1.3 times of that in blood.[75] Calculations of blood alcohol concentration from that determined in urine based on this average urine-blood alcohol ratio are admissible in some jurisdictions. However, the use of urine alcohol measurements for this purpose is discouraged by some authors, because the ratio of 1.3 is highly variable, and the urine alcohol concentration represents an average of the blood alcohol concentration during the time period in which urine collected in the bladder. A better correlation of urine with blood alcohol concentration is obtained by first emptying the bladder and then collecting urine after 20 to 30 minutes.

There is renewed interest in urine alcohol testing in conjunction with testing urine for drugs of abuse (see Drugs of Abuse). For this purpose, the detection of alcohol in urine represents ingestion of alcohol within the previous ~8 hours. Urine is not an approved specimen for alcohol measurement by the DOT.

Postmortem Alcohol

Alcohol is measured in postmortem blood and vitreous humor. Muscle has been proposed as a useful alternative specimen to postmortem blood.[167]

ANALGESICS (NONPRESCRIPTION)

Analgesics are substances that relieve pain without causing loss of consciousness. When used in excess, analgesics such as acetaminophen and salicylate can result in a toxic response.

Acetaminophen

Acetaminophen has analgesic and antipyretic actions. In common with the group of drugs referred to as nonsteroidal antiinflammatory drugs (NSAIDs: e.g., aspirin, ibuprofen, and indomethacin), acetaminophen's pharmacological actions are related to its competitive inhibition of cyclooxygenase enzymes, resulting in decreased production of prostaglandins, which are important mediators of inflammation, pain (low-to-moderate), and fever.[382] Contrary to other NSAIDs, acetaminophen has very weak antiinflammatory activity, a consequence of its weak inhibition of peripheral tissue cyclooxygenase compared with that in the brain. In normal dose, acetaminophen is safe and effective, but it may cause severe hepatic toxicity or death when consumed in overdose quantities. Less frequently, nephrotoxicity may also occur. The initial clinical findings in acetaminophen toxicity are relatively mild and nonspecific (nausea, vomiting, and abdominal discomfort) and thus are not predictive of impending hepatic necrosis, which typically begins 24 to 36

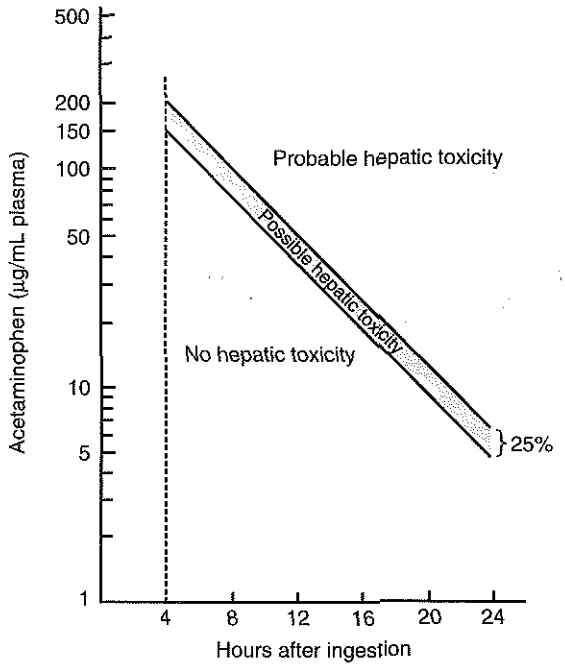

Figure 34-5 Rumack-Matthew nomogram. *(From Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. Pediatrics 1975;55:871-6. Reproduced by permission of Pediatrics.)*

hours after a toxic ingestion and becomes most severe by 72 to 96 hours.[360] Although uncommon with severe overdose, coma and metabolic acidosis may occur before development of hepatic necrosis.[154] Antidotal therapy with *N*-acetylcysteine (NAC; Mucomyst) (see below) is most effective when administered well before hepatic injury occurs as signified by elevations of AST and ALT. Thus the measurement of serum acetaminophen concentration becomes paramount for proper assessment of the severity of overdose and for making appropriate decisions for antidotal therapy. A useful nomogram is available that relates serum acetaminophen concentration and time following acute ingestion to the probability of hepatic necrosis (Figure 34-5).[386]

There are several qualifications concerning the use of this nomogram. First, blood samples should not be obtained earlier than 4 hours after ingestion to ensure that absorption is complete. Second, the nomogram applies only to acute and not chronic ingestions. Toxicity from chronic ingestion of acetaminophen or other drugs is cumulative and typically occurs at lower blood concentrations than in acute overdose. Third, the nomogram is not useful if the time of ingestion is unknown (within ± 2 hours) or is considered unreliable. In this case, two or more samples taken at 2- to 3-hour intervals may be used to estimate the acetaminophen elimination half-life. Hepatotoxicity is more probable when the acetaminophen half-life is greater than 4 hours, and hepatic coma is likely when the half-life is greater than 12 hours. Some,[373] but not all,[413] investigators believe the half-life to be a better predictor of hepatotoxicity than interpretation based on a single serum concentration. Fourth, serial determination of serum levels (e.g., every 2 hours) is warranted if extended-release medication has been ingested (Tylenol Extended Relief), because the time to reach peak serum concentration may be delayed beyond 4 hours.[180,438] Serial serum levels are also required when there has been co-ingestion of drugs that may delay gastric emptying (e.g., propoxyphene, present in combination with acetaminophen in Darvocet-N).[445] In this case, if the history is reliably known, clinical presentation (e.g., opioid toxidrome) and drug screen results should alert the physician to the need for serial monitoring. Fifth, alcoholic patients, fasting or malnourished patients, and patients on chronic therapy with microsomal enzyme-inducing drugs (anticonvulsants) may have increased susceptibility to acetaminophen hepatotoxicity,[63,90,400,411,475] presumably as a result of induction of cytochrome P_{450} (see below) and, in the case of alcoholics or fasting patients, depletion of glutathione (see below). In these cases, it has been proposed that the decision line in the nomogram be lowered by 50% to 70%.[411,415] Others do not advocate any change in the therapeutic decision line for such patients with acute ingestion. These risk factors may be more important in chronic acetaminophen poisoning. Although therapeutic guidelines for chronic acetaminophen poisoning have not been established, one recommended approach is to administer NAC if AST is elevated in symptomatic patients or if AST is >2-fold upper reference limit and acetaminophen >10 μg/mL for asymptomatic patients.[51]

Acetaminophen is normally metabolized in the liver to glucuronide (50% to 60%) and sulfate (~30%) conjugates.[161] A smaller amount (~10%) is metabolized by a cytochrome P_{450} mixed-function oxidase pathway that is thought to involve formation of a highly reactive intermediate (*N*-acetylbenzoquinoneimine)[311] (Figure 34-6). This intermediate normally undergoes electrophilic conjugation with glutathione and then subsequent transformation to cysteine and mercapturic acid conjugates of acetaminophen. With acetaminophen overdose, the sulfation pathway becomes saturated, and consequently a greater portion is metabolized by the P_{450} mixed-function oxidase pathway. When the tissue stores of glutathione become depleted, arylation of cellular molecules by the benzoquinoneimine intermediate leads to hepatic necrosis.[311]

Specific therapy for acetaminophen overdose is the administration of NAC, which probably acts as a glutathione substitute.[70] NAC may also provide substrate to replenish hepatic glutathione[108] or to enhance sulfate conjugation[279] or both. The time of administration of NAC is critical. Maximum efficacy is observed when NAC is administered within 8 hours, but efficacy then declines sharply between 18 and 24 hours after ingestion.[412] The antidote may have some beneficial effects even after liver injury has occurred, presumably by its ability to improve tissue oxygen delivery and use.[191] An initial loading dose (140 mg/kg) of NAC should be followed by 17 maintenance doses (70 mg/kg) given every 4 hours. A shorter treatment with only five maintenance doses was proposed in 2003.[496] If the serum acetaminophen results

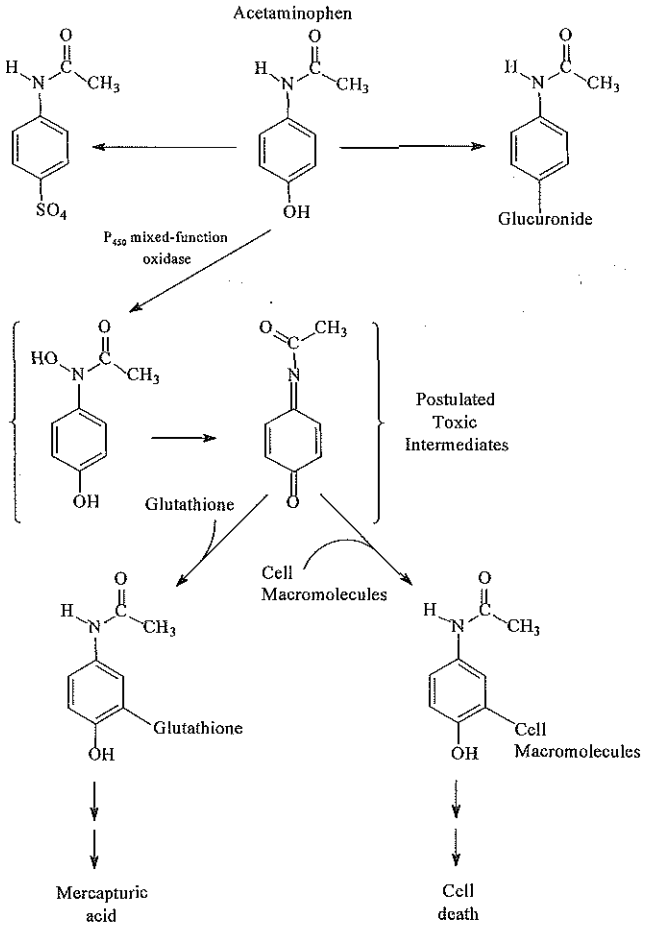

Figure 34-6 Pathways of acetaminophen metabolism. *(From Mitchell JR, Thorgeirsson SS, Potter WZ, Jollow DJ, Keiser H. Acetaminophen-induced hepatic injury: Protective role of glutathione in man and rationale for therapy. Clin Pharmacol Ther 1974; 16:676.)*

are not available locally within 8 hours of suspected ingestion, treatment with NAC should begin. This treatment may be discontinued if belated assay results indicate that it is not warranted.

Many photometric methods are available for the determination of acetaminophen.[66,478] In general, these methods are relatively easy to perform but may be subject to a number of interferences.[66] Some methods measure the nontoxic metabolites and the potentially toxic parent acetaminophen and thus may produce especially misleading results. Therefore only methods specific for parent acetaminophen should be used.[371] Immunoassays for acetaminophen, such as EMIT (Dade-Behring, Palo Alto, Calif.), FPIA (Abbott Laboratories, North Chicago, Ill.), and particle-enhanced turbimetric inhibition immunoassay (Beckman Coulter, Brea, Calif.) are widely used because they are rapid, easily performed, and accurate. A different approach uses arylacylamide amidohydrolase for hydrolysis of acetaminophen (but not conjugates) to *p*-aminophenol and acetate. Subsequent color formation depends on reaction of the generated *p*-aminophenol with 8-hydroxyquinoline[320] or *o*-cresol.[375] Adaptations of this enzyme assay are used on the VITROS (Johnson & Johnson Clinical Diagnostics, Rochester, N.Y.) and other automated chemistry analyzers.[68] Arylacylamide amidohydrolase methods are susceptible to interference by NAC,[301] bilirubin,[50] and IgM monoclonal immunoglobulins.[210] Most chromatographic methods are highly accurate and therefore may be considered reference procedures; however, they are more difficult to perform, especially on an emergency basis. A reference HPLC procedure[368] is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). A qualitative, one-step lateral flow immunoassay (cutoff 25 μg/mL) suitable for point-of-care application is available (SureStep, Applied Biotech, San Diego).

Salicylate

Acetylsalicylic acid (aspirin) has analgesic, antipyretic, and antiinflammatory properties. These therapeutic benefits derive from its ability to inhibit biosynthesis of prostaglandins by acetylation of active site serine and subsequent irreversible inhibition of cyclooxygenase enzymes (COX-1; COX-2 isoenzymes).[382] Salicylate, the metabolite of aspirin, also reduces prostaglandin synthesis by uncertain mechanisms. Because of these therapeutic benefits and the general lack of serious side effects at normal doses, aspirin is widely available and frequently consumed. Therapeutic serum salicylate concentrations are generally lower than 60 mg/L for analgesic-antipyretic effects, and 150 to 300 mg/L for antiinflammatory actions.[382]

Aspirin also interferes with platelet aggregation and thus prolongs bleeding time. The platelet inhibitory effect is a consequence of aspirin's ability to acetylate and irreversibly inhibit platelet cyclooxygenase, thereby reducing the formation of thromboxane A_2, a potent mediator of platelet aggregation. Platelets have little or no capacity for protein synthesis ; therefore, the duration of this enzyme inhibition is for the normal life span of the platelets (8 to 11 days).[385] Because of this platelet inhibitory activity, low-dose aspirin has been recommended as prophylactic therapy for some individuals at risk for thromboembolic disease.[352,428] There is an epidemiological association between aspirin ingestion and Reye's syndrome in children and adolescents with viral infections (e.g., varicella and influenza).[211] Aspirin use is therefore contraindicated in these patients.

The absorption of normal doses of regular aspirin from the GI tract is generally rapid, with peak serum concentration achieved within 2 hours.[382] This peak value may be delayed for 12 hours or longer for enteric-coated or slow-release formulations.[253] Moreover, toxic doses of aspirin may form concretions or bezoars and produce pylorospasm, thereby delaying absorption. Serum salicylate in such instances may not reach maximum concentration for 6 hours or longer,[122] an important consideration when the assessment of the severity of toxicity is based on such measurements.

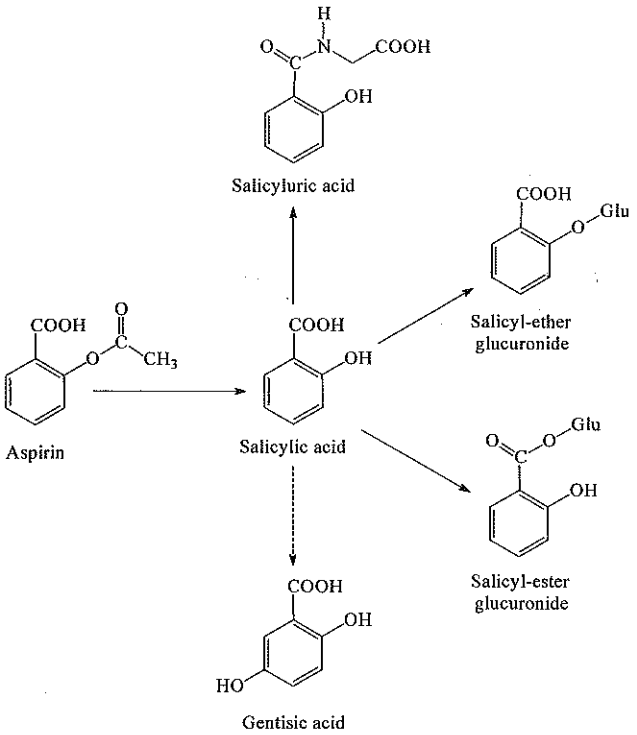

Figure 34-7 Metabolism of aspirin. (Glu, glucuronide.)

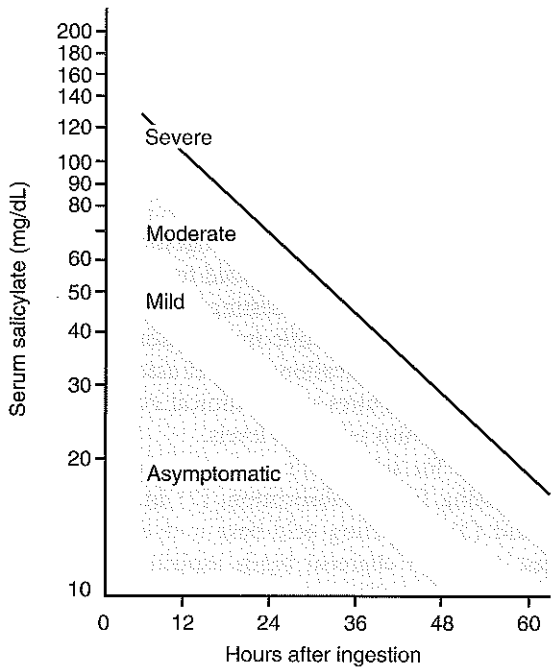

Figure 34-8 Nomogram for estimating the severity of acute salicylate intoxication. *(From Done AK. Salicylate intoxication: Significance of measurements of salicylate in blood in cases of acute ingestion. Pediatrics 1960; 26:800. Reproduced by permission of Pediatrics.)*

Once absorbed, aspirin has a very short half-life ($t_{1/2}$ = 15 min) because of its rapid hydrolysis to salicylate. Salicylate is eliminated mainly by conjugation with glycine to form salicyluric acid and to a lesser extent with glucuronic acid to form phenol and acyl glucuronides (Figure 34-7). A very small amount is hydroxylated to gentisic acid. These metabolic pathways may become saturated even at high therapeutic doses. Consequently, serum salicylate concentration may increase disproportionately with dosage. At high therapeutic or toxic doses, the salicylate elimination half-life is prolonged (15 to 30 hours versus 2 to 3 hours at low dose), and a much larger portion of the dose is excreted in urine as salicylate.[382]

Salicylates directly stimulate the central respiratory center and thereby cause hyperventilation and respiratory alkalosis. Moreover, salicylates cause uncoupling of oxidative phosphorylation. As a result, heat production (hyperthermia), oxygen consumption, and metabolic rate may be increased. In addition, salicylates enhance anaerobic glycolysis but inhibit Krebs cycle and transaminase enzymes, all of which lead to accumulation of organic acids and thus to metabolic acidosis.[459]

The primary acid-base disturbance observed with salicylate overdosage depends on age and severity of intoxication. Respiratory alkalosis predominates in children over age 4 and in adults, except in very severe cases that may progress through a mixed respiratory alkalosis–metabolic acidosis to metabolic acidosis. In 97 adult patients who had plasma salicylate concentrations greater than 700 mg/L, 19% were found to have respiratory alkalosis, 61% had combined respiratory alkalosis and metabolic acidosis, and 15% had metabolic acidosis. Mortality was associated with acidemia.[85] In children under age 4, the initial period of respiratory alkalosis is very brief and therefore may not be observed; in such cases, metabolic acidosis predominates.[459] CNS depression is more pronounced when acidemia is severe, a consequence of increased brain uptake of nonionized salicylic acid. Respiratory acidosis, a result of severe CNS depression or pulmonary edema, may sometimes occur and is indicative of a poor prognosis.

The symptoms of salicylate intoxication include tinnitus, diaphoresis, hyperthermia, hyperventilation, nausea, vomiting, and acid-base disturbances. CNS effects include lethargy, disorientation, and in severe cases, coma and seizures. Tinnitus may occur at salicylate concentrations greater than 200 mg/L, but more serious toxic manifestations are generally not evident unless the salicylate concentration exceeds 300 mg/L.[382]

Measurement of serum salicylate concentration is important for assessment of the severity of intoxication. A nomogram that relates serum salicylate concentration and time after ingestion with the severity of intoxication was developed by Done[122] (Figure 34-8), primarily for use with pediatric patients. The nomogram applies only to acute ingestion of salicylate and should not be used to estimate severity of chronic toxicity. The nomogram is less useful for adult patients,[127] who tend to have less severe acidemia (mixed respiratory alkalosis–metabolic acidosis) than young children (acidosis). Moreover, interpretation of the nomogram is

complicated in instances of mixed drug ingestion. For these reasons, use of this nomogram is discouraged by some toxicologists.

Aspirin absorption may be delayed when overdose quantities are consumed, especially of enteric-coated or slow-release preparations. This must be considered when interpreting serum salicylate values, especially for specimens obtained earlier than 6 hours after ingestion. Repeat testing within 2 to 3 hours is recommended to ensure that absorption is complete; subsequent testing provides an indication of effectiveness of therapeutic intervention. Because of the aforementioned complications, proper assessment of salicylate intoxication requires sound clinical evaluation in combination with serum salicylate levels.

Treatment for salicylate intoxication is directed toward (1) decreasing further absorption, (2) increasing elimination, and (3) correcting acid-base and electrolyte disturbances. Activated charcoal binds aspirin and prevents its absorption. Elimination of salicylate may be enhanced by alkaline diuresis and in severe cases by hemodialysis.[459] Sodium bicarbonate may be given to alleviate metabolic acidosis. Indications for hemodialysis include serum salicylate >1000 mg/L, severe CNS depression, intractable metabolic acidosis, hepatic failure with coagulopathy, and renal failure.[156]

A urine drug screen may be helpful to recognize the presence of drugs from combination medications with aspirin (e.g., antihistamines, sympathomimetic amines, and propoxyphene) or that otherwise are co-ingested.

Classic methods for the measurement of salicylate in serum are based on the method of Trinder.[452] These procedures rely on the reaction between salicylate and Fe^{3+} to form a colored complex that is measured at 540 nm. To lessen endogenous background interference, either a protein precipitation step or a serum blank is necessary. Nevertheless, blank readings equivalent to about 20 to 25 mg/L are generally observed. Moreover, interference by salicylate metabolites, endogenous compounds, and some drugs, especially structurally related drugs such as diflunisal (difluorophenyl salicylate),[393] may occur. Azide, present as a preservative in some commercial control sera, also causes interference. Despite these limitations, photometric methods continue to be successfully used to assess salicylate overdose. In a comparative study with 115 patient specimens, Trinder method results agreed very closely with those of a reference HPLC procedure.[220] However, significant interference with the Trinder method was observed for one patient who consumed an overdose of dichloralphenazone. Thus for best interpretation of test results, as much information as possible should be obtained regarding drug ingestion history.

Other methods for salicylate quantitation include fluorescent polarization immunoassay[238] and a salicylate hydroxylase–mediated photometric procedure[321] (Figure 34-9). These procedures are subject to some of the same interferences as is the Trinder method, but the salicylate hydroxylase method is considered more specific.[321] This

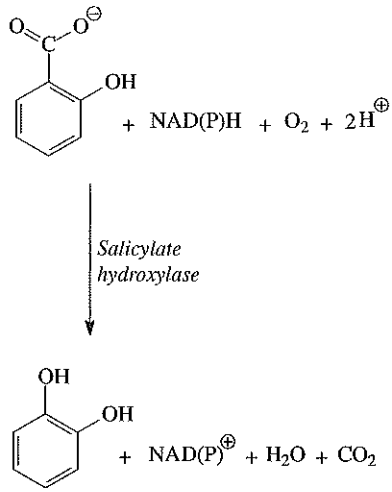

Figure 34-9 Salicylate hydroxylase–mediated oxidative decarboxylation of salicylate.

enzyme method has been adapted to automated analyzers, such as the Synchron (Beckman Coulter). Gas and liquid chromatographic methods are the most specific methods for salicylate,[81,378] but their general availability, especially for emergency use, is limited and probably not necessary.[393,434]

Because of its ease of performance and wide acceptance, the photometric method of Trinder[132] for measuring salicylates is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). In addition, an HPLC method[81] suitable for pharmacokinetic studies or for therapeutic monitoring of salicylate is also included. A qualitative spot test based on the Trinder reaction is also on the Evolve site (http://evolve.elsevier.com/Tietz/textbook/). A qualitative, one-step lateral flow immunoassay (cutoff 100 mg/L) suitable for point-of-care application is commercially available (Applied Biotech, San Diego).

Drugs Related to the Anticholinergic Toxidrome

While the tricyclic antidepressants, the phenothiazines, and the antihistamines have divergent therapeutic applications, in overdose they often share similar anticholinergic and antihistaminic toxidromes as principal components of their overall toxic effects. These overlapping toxicities are likely related to their common methyl or dimethyl aminoethyl (—$CH_2CH_2N[CH_3]_2$; —$CH_2CH_2NHCH_3$) moieties, which are structurally related to similar groups in acetylcholine (—$CH_2CH_2N[CH_3]_3$) and histamine (—$CH_2CH_2NH_2$).

Tricyclic Antidepressants

Tricyclic antidepressants represent a class of drugs widely prescribed for the treatment of endogenous depression and neuralgic pain, migraine headache, enuresis, and attention deficit disorder (see Chapter 33). Tricyclic antidepressants include imipramine, amitriptyline, and their *N*-

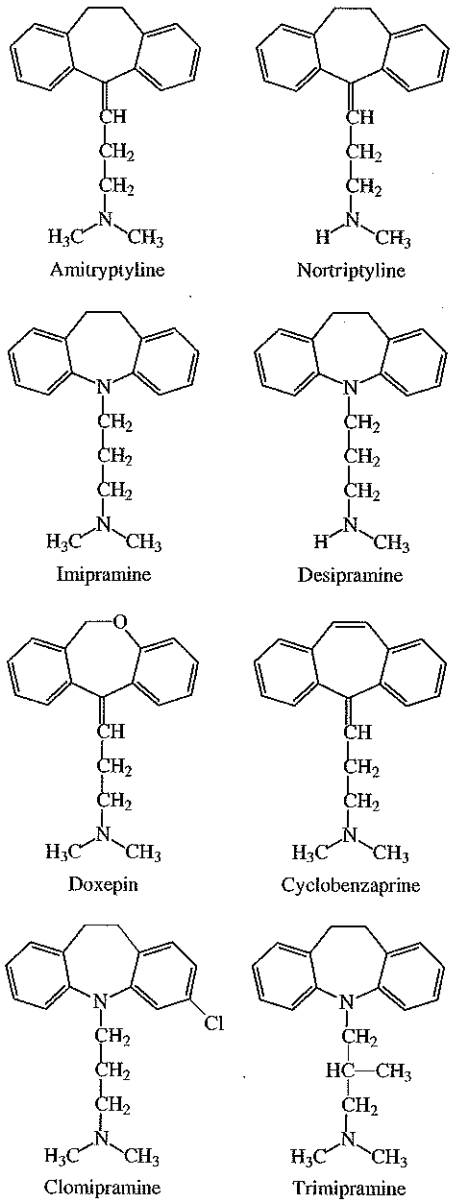

Figure 34-10 Structure of some tricyclic antidepressants and the muscle relaxant cyclobenzaprine.

demethylated derivatives, desipramine and nortriptyline; clomipramine; doxepin; and trimipramine (Figure 34-10). Other cyclic antidepressant drugs include amoxapine and maprotiline.

Tricyclic antidepressants block neuronal uptake of norepinephrine and variably serotonin (those with tertiary amine side chains), and the degree of inhibition seems to correlate with antidepressant activity. However, the block in amine uptake occurs shortly after drug administration, whereas the antidepressant effects generally require several weeks to develop.[20,250,337] Thus the mechanism of action is incompletely understood and may involve changes in presynaptic and postsynaptic neurogenic amine receptor response. In addition to their mood-elevating actions, tricyclic antidepressants also have sedative effects that may be related to antihistamine activity in the CNS. Tertiary amines (amitriptyline, doxepin, and imipramine) produce greater sedation than the secondary amines. Cyclic antidepressants also exert central and peripheral anticholinergic effects and peripheral α_1-adrenergic blockade.

Because of their continued use, narrow therapeutic range, and the nature of the illness for which they are typically prescribed, tricyclic antidepressants may cause severe or fatal toxicity.[138,278,357,419] For example, in March of 2004 the U.S. FDA issued a Public Health Advisory because of both suicidal ideation and suicide attempts in children taking antidepressant drugs for the treatment of major depressive disorder.

The antimuscarinic actions of tricyclic antidepressants are responsible for side effects frequently experienced even at therapeutic doses and are therefore commonly present in overdose. These effects include tachycardia, hyperpyrexia, dilated pupils, dry skin and mouth, flushing, decreased GI motility, and urinary retention.

The CNS manifestations of tricyclic antidepressant overdose may vary from mild agitation or drowsiness to delirium, coma, respiratory depression, or seizures. These manifestations are thought to result in part from central anticholinergic and antihistaminic actions of these drugs.

Cardiovascular toxicity is the most serious manifestation of tricyclic antidepressant overdose and accounts for the majority of fatalities. Tricyclic antidepressants inhibit Na^+ entry via sodium channels in the myocardium, which results in decreased conductivity, decreased contractility, and arrhythmia (quinidine-like effect). In addition, their anticholinergic and sympathomimetic (inhibition of norepinephrine uptake) effects contribute to dysrhythmias. In mild overdose, these effects result in tachycardia and slight increase in blood pressure. With more severe overdose, serious arrhythmias and conduction delays may develop, of which the most distinct feature is prolongation of the QRS interval in the electrocardiogram. In addition, cardiac output decreases, which coupled with peripheral vasodilation (α_1-adrenergic blockade) leads to life-threatening hypotension. Death often results from arrhythmias or hypotension. The cardiotoxic manifestations may occur within a few hours of overdose, or they may be delayed for 24 hours or longer. It is important to recognize that a patient's symptomatology (perhaps initially only mild anticholinergic effects) is due to tricyclic antidepressants so that a proper period of monitoring for delayed and possibly catastrophic cardiotoxicity can be followed. Thus laboratory identification of these drugs, especially in the absence of a reliable history, provides crucial information.

In addition to general supportive measures (gastric lavage, activated charcoal, and IV fluids), therapy for tricyclic antidepressant overdose includes administration of $NaHCO_3$ for dysrhythmias (alkalinization causes tricyclic antidepressants to dissociate from the membrane sodium channels and Na^+ provides a favorable gradient for Na^+ channel activated

membrane depolarization). Physostigmine, a reversible cholinesterase inhibitor, can effectively reverse the central and peripheral anticholinergic manifestations of tricyclic antidepressant toxicity. However, its use is generally contraindicated in tricyclic antidepressant overdose because of the risk of enhancing cardiac conduction delays, which may result in asystole. Hemodialysis or hemoperfusion is not beneficial because the tricyclic antidepressant drugs have a large volume of distribution and are extensively bound to plasma proteins.

Newer, safer drugs that are selective inhibitors of serotonin reuptake [e.g., fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil)] have no or minimal antimuscarinic, antihistaminic, or adverse cardiovascular effects. They are now the drugs of choice for treatment of depressive disorders.

Tricyclic antidepressants may be measured quantitatively in serum by chromatographic methods (most commonly HPLC) or by immunoassay (EMIT; FPIA; see Chapter 33). These immunoassays may also be used for qualitative or semiquantitative detection of tricyclic antidepressants, which are useful for screening. Immunoassays are rapid and relatively easy to perform but may be subject to interference by other drugs, such as chlorpromazine,[347] thioridazine,[387] cyproheptadine,[476] cyclobenzaprine,[347] and diphenhydramine.[425] Tricyclic antidepressants are adequately detected in urine, using TLC (e.g., Toxi-Lab) and by colloidal gold immunoassay (Triage, BioSite Diagnostics, San Diego). In cases of overdose, qualitative identification (serum or urine) is sufficient, because the severity of intoxication is more reliably indicated by an increase in the QRS interval (>100 ms) than by the serum concentration.[57]

Cyclobenzaprine, a tricyclic amine structurally very similar to amitriptyline (see Figure 34-10), is used as a centrally acting skeletal muscle relaxant. Like amitriptyline, cyclobenzaprine causes sedation, produces central and peripheral muscarinic blockade, and potentiates adrenergic actions. In overdose, cyclobenzaprine may cause a typical anticholinergic toxidrome and cardiac arrhythmias, hypotension, and coma. However, cyclobenzaprine overdose is not as frequent nor as lethal as amitriptyline overdose.

The analytical distinction between amitriptyline and cyclobenzaprine is often difficult. Cyclobenzaprine cross-reacts with immunoassays for tricyclic antidepressants (EMIT, TDx, and Triage) and generally co-elutes or co-migrates with amitriptyline in HPLC and TLC. However, cyclobenzaprine and amitriptyline have different ultraviolet spectra; therefore, they may be distinguished by HPLC using a diode array detector by either multiwavelength scanning (e.g., Remidi)[119,366] or dual-wavelength discrimination.[119] Although these two drugs co-migrate using the Toxi-Lab system, they may be distinguished by differences in fluorescence at stage III (amitriptyline fluoresces pink whereas cyclobenzaprine fluoresces orange).[40] Finally, amitriptyline and cyclobenzaprine are well resolved using capillary column GC (Figure 34-11) and may be distinguished by careful examination of their respective mass spectra (ratio of 202/215 amu ions differ) (Figure 34-12).[486]

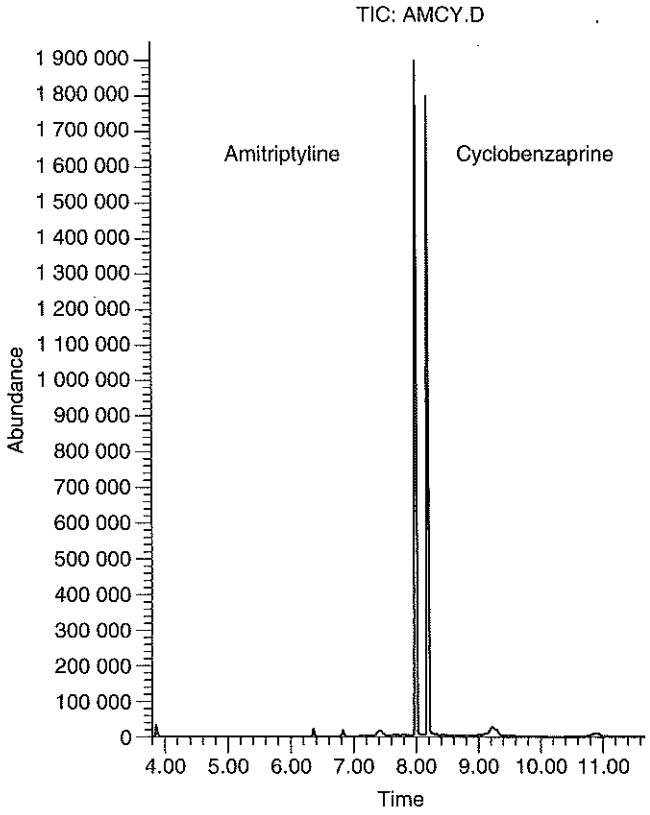

Figure 34-11 Total-ion chromatogram for amitriptyline and cyclobenzaprine. Time = minute.

Phenothiazines

Phenothiazines are tricyclic compounds that have chemical and pharmacological properties in common with the tricyclic antidepressant drugs (Figure 34-13; see also previous section on Tricyclic Antidepressants). They are primarily used for their neuroleptic (behavior modifying) properties in the treatment of severe psychiatric illness (psychoses and mania). In addition, phenothiazines are administered to control nausea and vomiting, for sedation, and for potentiation of analgesia and general anesthesia.[21]

The phenothiazines inhibit dopaminergic receptors in the CNS, a property thought to account for their neuroleptic effect.[21] In addition, phenothiazines inhibit muscarinic, α-adrenergic, histaminic, and serotonergic receptors, which accounts for many of their toxic or undesirable side effects.

The principal manifestations of phenothiazine toxicity involve the CNS and cardiovascular system.[21,37,286] Signs of CNS toxicity include sedation, coma, respiratory depression (uncommon), seizures, hypothermia or hyperthermia, and extrapyramidal movement disorders (acute dystonia, parkinsonism, akathisia, tardive dyskinesia, and neuroleptic malignant syndrome); the extrapyramidal symptoms result from an imbalance between inhibitory dopamine and

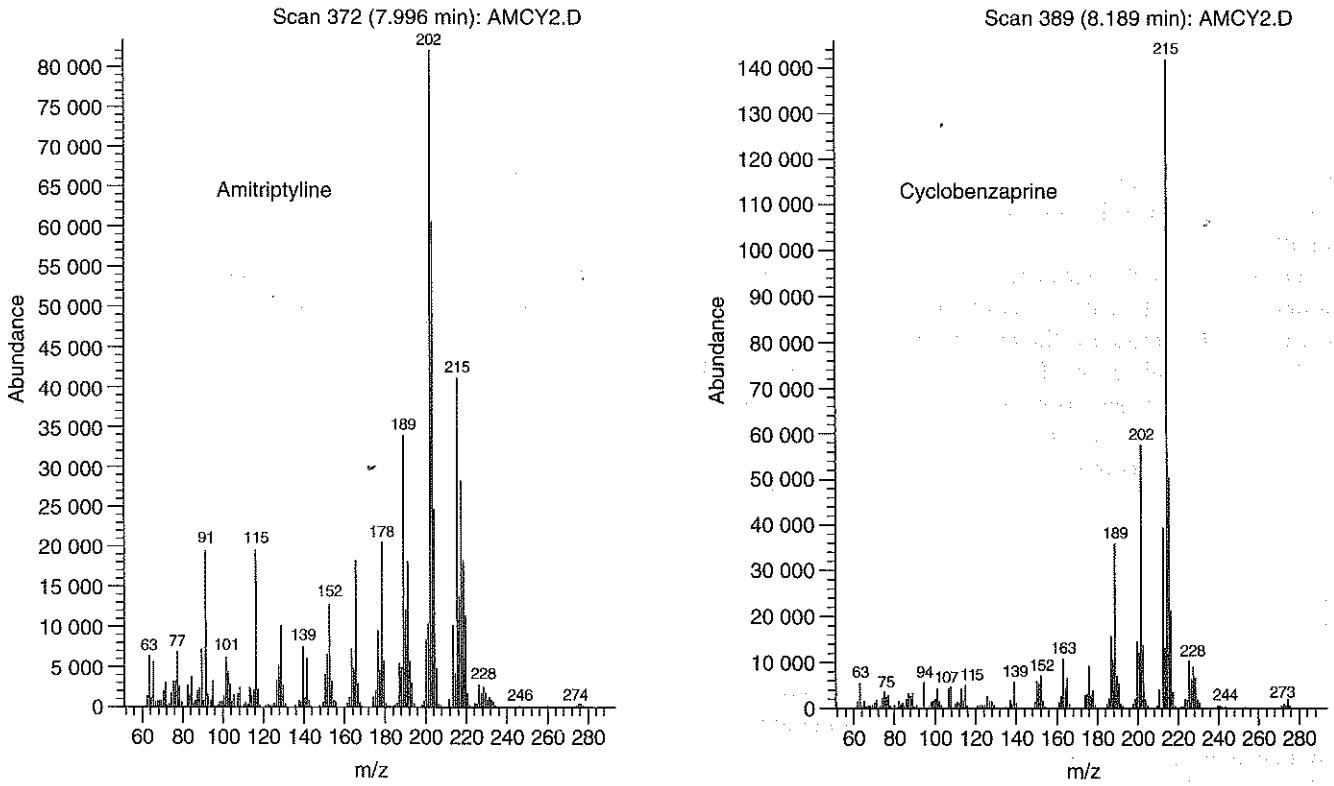

Figure 34-12 Mass spectra for amitriptyline and cyclobenzaprine. The spectra were scanned from 60 to 500 amu to avoid the large, dominant 58 amu ion present in each.

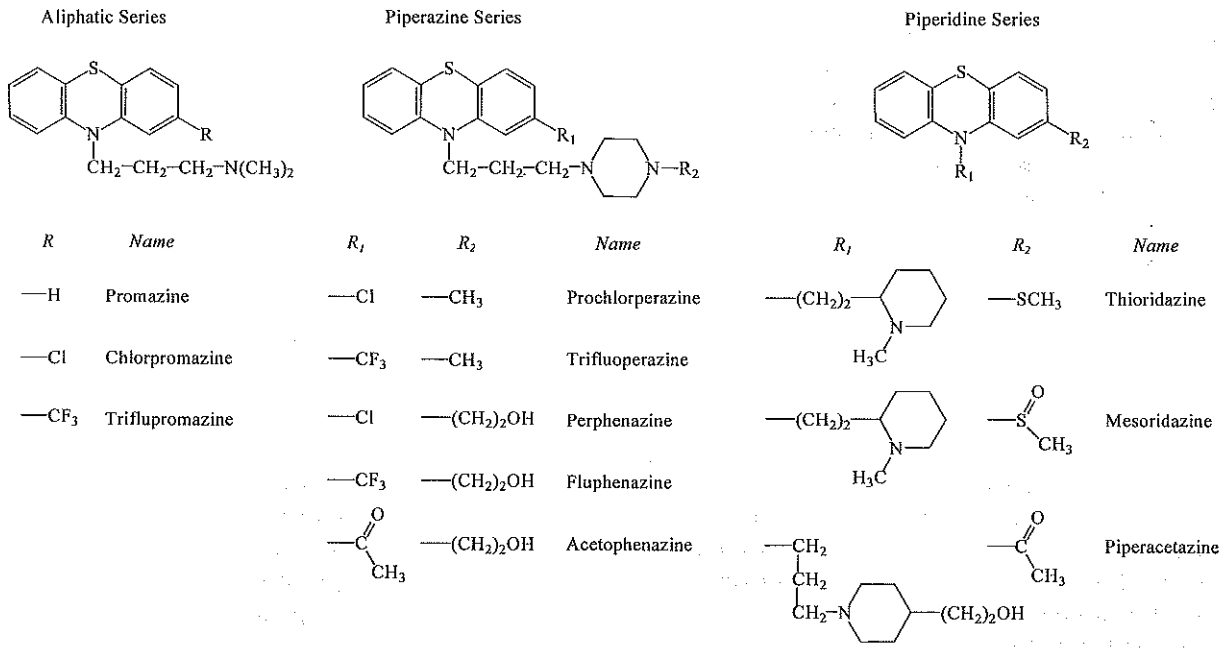

Figure 34-13 Chemical structure of representative phenothiazines.

excitatory acetylcholine responses within the extrapyramidal motor system. The cardiovascular effects include orthostatic or frank hypotension and arrhythmias, a consequence of the quinidine-like depressant action on the myocardium and α-adrenergic blockade. Additional peripheral antimuscarinic manifestations include decreased bowel sounds, urinary retention, skin flushing, blurred vision, and dry mouth.

The cardiovascular, CNS, and anticholinergic symptoms of phenothiazine toxicity are similar to, but generally much less severe than, those for the tricyclic antidepressants. Phenothiazines are relatively safe, and few deaths have occurred when toxic doses have been ingested alone. Much more severe toxicity occurs when phenothiazines are co-ingested with tricyclic antidepressant drugs or other CNS depressant drugs, such as ethanol, opioids, barbiturates, or benzodiazepines.

Therapy for phenothiazines is generally supportive and similar to that for tricyclic antidepressant overdose. Physostigmine can reverse the central and peripheral anticholinergic manifestations of phenothiazines; however, because these manifestations are rarely life-threatening and because physostigmine may cause severe bradycardia or asystole it is not recommended for treatment of phenothiazine overdose. Because of the large volume of distribution and extensive protein binding, hemodialysis or hemoperfusion is not beneficial for phenothiazine overdose.

The phenothiazines are extensively metabolized by the liver to a number of metabolites, some of which are pharmacologically active. Less than 1% of a dose is excreted unchanged in the urine. The correlation between dose, serum concentration, and pharmacological effect is poor; therapeutic drug monitoring[470] or serum quantitation in instances of overdose is not warranted.[37,286] Qualitative detection of phenothiazines or their metabolites in urine is sufficient to document ingestion for symptomatic patients. Suitable methods of detection include TLC (e.g., Toxi-Lab) and the spot test using the Forrest reagent (potassium dichromate, sulfuric acid, perchloric acid, and nitric acid).[53] The ability to also detect other co-ingested drugs, such as opioids, tricyclic antidepressants, barbiturates, and benzodiazepines, is important to alert the physician to the enhanced potential for severe toxicity from their combined ingestion.

Antihistamines

Histamine released from mast cells plays an important physiological role in immediate hypersensitivity and allergic responses. In addition, histamine functions as a neurotransmitter in the CNS and it is a potent stimulus for gastric acid secretion. These actions depend on the interaction of histamine with two types of receptors, H_1 and H_2.[69] H_1 and H_2 receptors are coupled via G proteins to phospholipase C and adenylyl cyclase, respectively. The principal H_2 receptor response is stimulation of gastric acid secretion, whereas other actions of histamine (e.g., smooth muscle contraction, vasodilation, increased capillary permeability, pain, and itching) are primarily mediated by H_1 receptors.

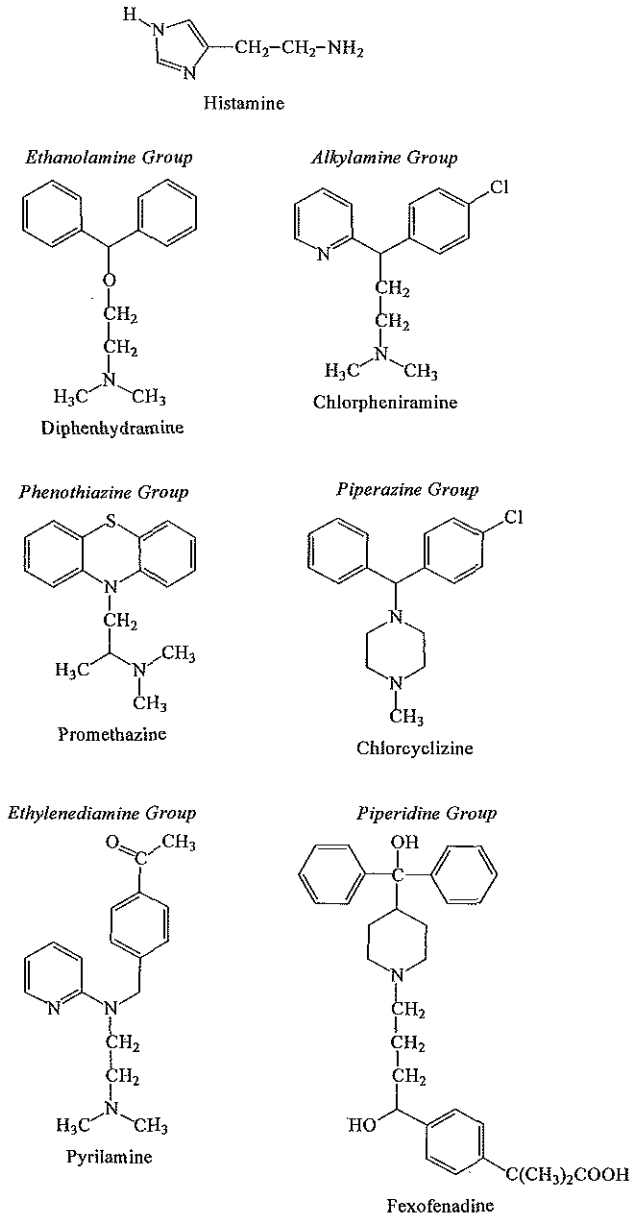

Figure 34-14 Chemical structure of histamine and representative H_1 antagonists.

The antihistamine drugs are classified as H_1 or H_2 antagonists, based on their principal receptor site binding.[69] The H_1 antagonists contain a substituted ethylene amine (—$CH_2CH_2NR_2$—), in common with both histamine (Figure 34-14) and acetylcholine (Figure 34-15); therefore they exhibit both antihistaminic and anticholinergic pharmacological actions. The second-generation H_1 antagonists, such as fexofenadine (Allegra), have very little anticholinergic activity.

The therapeutic actions of H_1 antagonists include smooth muscle relaxation, decreased bronchial secretions, decreased allergic response, and sedation. They are therefore used to treat immediate hypersensitivity reactions, as cold remedies, to suppress motion sickness, and for sedation (the second-generation H_1 antagonists [e.g., fexofenadine] do not pene-

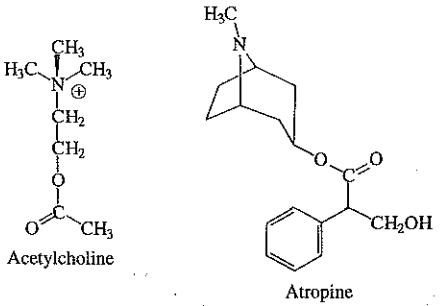

Figure 34-15 Structure for the neurotransmitter acetylcholine and its antagonist, atropine.

trate the blood-brain barrier well and therefore do not cause sedation). The H_2 antagonists are widely used to treat peptic ulcer disease. The most prominent H_2 antagonists are cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid), and nizatidine (Axid).

The principal manifestations of overdose due to H_1 antagonists are CNS depression or stimulation and anticholinergic symptoms.[69,246,473] Symptoms of CNS depression include sedation, drowsiness, ataxia, and coma. CNS stimulation, more common in children, results in excitement, hallucinations, toxic psychosis, delirium, and convulsions. The antimuscarinic toxidrome includes dry mouth, flushed dry skin, urinary retention, sinus tachycardia, dilated pupils, blurred vision, and fever. Death may occur because of respiratory depression or cardiovascular collapse.

Treatment for H_1 antagonist overdose is general and supportive (e.g., gastric lavage and activated charcoal).[246,473] Hemodialysis or hemoperfusion is not efficacious because these drugs have a large volume of distribution and are highly protein bound. Physostigmine may be used cautiously if central and peripheral anticholinergic symptoms are prominent, and there is no evidence of cardiac conduction delays (electrocardiogram; no evidence [history or drug screen] of exposure to drugs that can cause conduction delays [e.g., cocaine, tricyclic antidepressants, phenothiazines, and procainamide]).

Antihistamines are present in prescription and nonprescription forms, alone or in combination with analgesics, such as aspirin and acetaminophen. In instances of overdose, a urine drug screen that detects salicylate, acetaminophen, and the antihistamines is helpful, especially when the source of intoxication is unknown. The detection of either analgesic in the urine of a symptomatic patient should lead to their quantitation in serum to assess their potential toxicity (see sections on Salicylate and Acetaminophen). Quantitation of antihistamines in serum is not useful, because there is a poor correlation between dose, drug level, and degree of toxicity.[473]

Overall the antihistamines are relatively safe. However, their CNS depressant actions are enhanced by co-ingestion of ethanol, sedative-hypnotic drugs, and opioids; their anticholinergic actions are potentiated by co-ingestion of tricyclic antidepressants and phenothiazines. Therefore the detection of any of these drugs in combination on a urine drug screen should alert the physician to a potentially more serious intoxication.

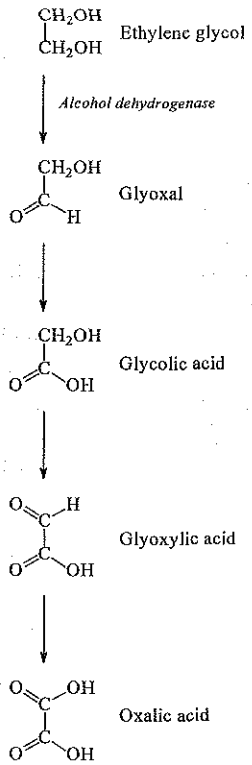

Figure 34-16 Metabolism of ethylene glycol.

Ethylene Glycol

Ethylene glycol, present in antifreeze products, may be ingested accidentally or for the purpose of inebriation or suicide. Ethylene glycol itself is relatively nontoxic, and its initial CNS effects resemble those of ethanol. However, metabolism of ethylene glycol by ADH results in the formation of a number of acid metabolites, including oxalic acid and glycolic acid (Figure 34-16).

These acid metabolites are responsible for much of the toxicity of ethylene glycol,[199,219] the clinical manifestations of which include neurological abnormalities (CNS depression; in severe cases, coma and convulsions), severe metabolic acidosis, acute renal failure, and cardiopulmonary failure.[280] The serum concentration of glycolic acid correlates more closely with clinical symptoms and mortality than does the concentration of ethylene glycol.[199,369] Because of the rapid elimination of ethylene glycol ($t_{1/2}$ ~3 hours), its serum concentration may be low or undetectable at a time when that for glycolic acid remains elevated.[164,199,369] Thus the determination of both ethylene glycol and glycolic acid provides useful clinical and confirmatory analytical information in cases of ethylene glycol ingestion. Other laboratory findings commonly observed with ethylene glycol poisoning include increased serum osmol and anion gaps, decreased serum calcium, and the presence of calcium oxalate crystals in the urine. The decreased serum calcium results from calcium

oxalate deposition in tissue or from a possible interference in normal parathyroid hormone response[409] or both.

Early recognition of ethylene glycol intoxication and thus of the need for timely therapeutic intervention is important because of the compound's short half-life (about 3 hours). Blood concentration of ethylene glycol may decline rapidly during the first 24 hours following ingestion.[361] Therefore relatively low serum concentrations (0.05 to 2 g/L) may be observed in serious intoxication if several hours have elapsed between the time of ingestion and that of blood sampling. In such cases, the measurement of glycolic acid is especially important. Serum concentrations associated with deaths from ethylene glycol ingestion have ranged from 0.06 to 4.3 g/L,[29,369] highlighting the lack of correlation between ethylene glycol concentration and severity of toxicity. It is thus impossible to define a serum ethylene glycol concentration associated with a high probability of death. Contrarily, a mortality rate of 33% occurred when serum glycolic acid was >10 mmol/L in a study of 41 patients; 94% of survivors with glycolic acid >10 mmol/L developed acute renal failure.[369]

Appropriate therapy for ethylene glycol intoxication includes administration of fomepizole (4-methylpyrazole) or ethanol to competitively inhibit the ADH-mediated metabolism of ethylene glycol, aggressive therapy with sodium bicarbonate to help alleviate the acidosis, and hemodialysis or forced diuresis to enhance the removal of ethylene glycol and acid metabolites.[23,64,205] A serum ethanol concentration of ~100 mg/dL is sufficient to saturate ADH and thus prolongs the elimination half-life of ethylene glycol from ~3 hours (metabolism and renal excretion) to about 17 hours (renal excretion).[361] Administration of ethanol or preferably fomepizole is generally recommended when the serum ethylene glycol concentration is greater than 0.2 g/L.[23] Hemodialysis effectively removes ethylene glycol and glycolic acid and is recommended when the serum ethylene glycol concentration is greater than 0.5 g/L, with severe metabolic acidosis (pH <7.25 to 7.30), or with renal failure, regardless of the serum ethylene glycol concentration.[23] Serum glycolic acid ≥10 mmol/L predicts with high probability acute renal failure and the need for hemodialysis, whereas those patients with levels <10 mmol/L likely only require adequate antimetabolite therapy.[64,369] In the absence of glycolic acid measurements, an anion gap >20 mmol/L or pH <7.3 predicts acute renal failure in known ethylene glycol ingestions somewhat less reliably.[369] Patients with initial serum ethylene glycol concentration of 6.5 g/L,[361] 5.6 g/L,[429] 8.1 g/L,[369] and 18.9 g/L[225] survived because of early therapy with ethanol infusion and hemodialysis.

Ethylene glycol intoxication is relatively rare, but when it does occur, it is important for the laboratory to provide rapid (<2 hours) analytical support. A GC-MS method is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/); it allows for the simultaneous determination of ethylene glycol and glycolic acid.[370] It is relatively simple and rapid, and it is free from interference by propylene glycol (a diluent for parenteral drugs, such as diazepam and phenytoin) or 2,3-butanediol (may be present in serum from some alcoholics); these glycols may interfere with the determination of ethylene glycol in some chromatographic procedures.[231] A comparable procedure using flame ionization detection has also been described.[494] Ethylene glycol may be rapidly measured with the use of glycerol dehydrogenase,[52,289] but these enzyme methods are subject to interference by glycerol,[52,291] propylene glycol,[3,291] 2,3-butanediol,[291,308,330] β-hydroxybutyrate,[52] and high concentrations of lactate and lactate dehydrogenase.[133] A serum osmol gap >10 mmol/L may be a nonspecific indicator of the presence of ethylene glycol (see section on Screening Methods).[23,369]

Toxic Metals/Iron

Several toxic metals, including arsenic, iron, lead, and mercury, are discussed in Chapters 30 and 35. Their measurement in urine, blood, and hair (in some cases) is valuable to help diagnose acute or chronic metal poisoning. Specific therapy for these toxins is listed in Table 34-1. Because the assessment of acute iron overdose requires emergency laboratory support, it is discussed in this chapter.

When severe acute iron intoxication occurs in children, significant morbidity or death may result.[358a] The limited physiological regulation of iron absorption from the GI tract may become overwhelmed with acute ingestion of large doses of iron. In such instances, the likelihood of iron toxicity is enhanced because no specific mechanisms exist for iron elimination. The initial toxic effects on the GI tract are a result of a direct corrosive action of iron on the mucosa, which may cause mucosal edema, infarction, ulceration, or hemorrhage. As a result, clinical symptoms of nausea, vomiting, abdominal pain, diarrhea, hematemesis, and melena may be evident. The systemic actions of excess iron affect the cardiovascular system, general metabolic functions, the liver, and the CNS. The cardiovascular effects of iron toxicity include decreased cardiac output, venous pooling of blood, and capillary leakage, all of which may lead to hypotension, shock, cyanosis, lethargy, tachycardia, and lactic acidosis. Within the liver, excess iron may cause swelling or necrosis of hepatocytes, resulting in abnormal liver function tests and a coagulopathy. Moreover, iron may accumulate within hepatic mitochondria and promote oxygen–free radical formation, lipid peroxidation of mitochondrial membranes, and interference with the electron transport system. Consequently, dysfunction of the Krebs cycle and oxidative phosphorylation lead to metabolic acidosis and secondarily cause hyperglycemia. The effects on the CNS range from lethargy and obtundation to frank coma. These effects may be secondary to cardiovascular, hepatic, and metabolic toxicity and to a direct CNS action of iron.

Specific treatment for iron toxicity involves administration of deferoxamine to chelate unbound iron.[358a] The deferoxamine–Fe complex is then excreted in the urine, often

resulting in a characteristic vin rose color. The decision to administer deferoxamine is based on the history, clinical symptoms, and measurement of serum iron. In general, only mild toxicity is evident when the serum iron is below 300 μg/dL, and deferoxamine administration is normally not necessary. When the serum iron reaches 500 μg/dL, serious systemic toxicity is likely and may be fatal at concentrations of 1000 μg/dL or greater. Serum iron should be measured on admission and again 4 to 6 h after ingestion when absorption should be complete and the maximum serum level obtained. Serial measurement of serum iron is warranted if sustained-release medication has been ingested or if large bezoars are evident by abdominal x-ray.

Iron toxicity is presumably not likely unless the total serum iron concentration exceeds the total iron-binding capacity (TIBC; see Chapter 31). Thus, measurement of TIBC would be important in cases of iron poisoning but is discouraged because of methodological limitations.[382a,440a] In the determination of TIBC, excess iron is added to serum to bind all available iron-binding sites. Excess unbound iron is then removed by an absorbent material (e.g., $MgCO_3$) prior to measurement of bound iron. In the presence of excess endogenous iron, this absorbent material may be inadequate to remove all unbound iron, resulting in a falsely elevated TIBC. However, this limitation does not apply to the homogenous measurement of the unbound iron-binding capacity (UIBC), at least up to a total iron of 500 μg/dL,[382a] or to the immunochemical determination of transferrin, both of which may be performed on automated general chemistry analyzers. The TIBC (μg/dL) is equal to UIBC (μg/dL) + Fe (μg/dL) or to transferrin (mg/dL) × 1.43. Outcome-based validation of these derived TIBC measures in acute iron toxicity remains to be performed. Nevertheless, an expert toxicology committee of the National Academy of Clinical Biochemistry recommends their determination for the evaluation of iron toxicity.[491] Other general laboratory parameters that are considered helpful in the assessment of iron toxicity include WBC > $15{,}000 \times 10^9$/L and a serum glucose >150 mg/dL.

Deferoxamine interferes with photometric measurements of iron and UIBC,[382a] an important consideration if serum iron and UIBC measurements are used to monitor therapy with deferoxamine. Deferoxamine has a short $t_{1/2}$ (~1 h); therefore, a delay of at least 4 h after deferoxamine administration would be appropriate before measurements of serum iron and UIBC are repeated.

Organophosphate and Carbamate Insecticides

Acetylcholine is an essential neurotransmitter that affects parasympathetic synapses (autonomic and CNS), sympathetic preganglionic synapses, and the neuromuscular junction (see also prior section on Toxic Syndromes). Hydrolysis of acetylcholine by acetylcholinesterase, which is present in nerve tissue, normally limits the duration of action of this neurotransmitter and allows for normal synaptic function. Organophosphate (e.g., Malathion, Parathion, Diazinon, Dursban) and carbamate (e.g., Sevin and Furadan) insecticides (Figure 34-17) exert their toxicity by inhibiting the action of acetylcholinesterase and thereby causing a pronounced cholinergic response.[24,78,92,140,437] Enzyme inhibition is the consequence of phosphorylation (organophosphates) or carbamylation (carbamates) of the cholinesterase-active site serine hydroxyl group. The resulting alkylphosphoryl-serine bond undergoes spontaneous hydrolysis with subsequent enzyme reactivation at very slow to essentially nonexistent rates, depending on the size of the alkyl groups. Moreover, some phosphorylated enzyme complexes, especially those with a secondary alkyl group, lose an alkyl group at variable rates (generally 24 to 48 hours) to form a phosphoryl oxyanion serine bond that is completely resistant to even pharmacologically mediated hydrolysis (Figure 34-18). This dealkylation reaction, termed enzyme "aging," is probably mediated by enzyme active-site histidine and glutamate side chains.[401] In contrast to the phosphoryl-serine bond, the carbamyl-serine bond undergoes spontaneous hydrolysis with regeneration of enzyme activity (24 to 48 hours). For this reason and because of poor CNS penetration, carbamate insecticide neurotoxicity is less severe and of shorter duration than that for the organophosphates.

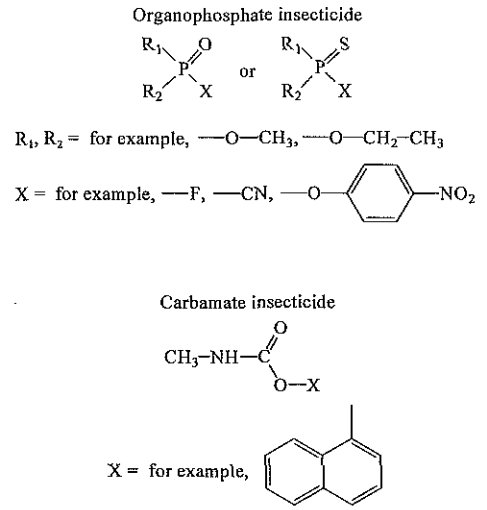

Figure 34-17 General chemical structures for organophosphate and carbamate insecticides.

Excess synaptic acetylcholine stimulates muscarinic receptors (peripheral and CNS) and stimulates but then depresses or paralyzes nicotinic receptors.[437] Activation of peripheral muscarinic receptors causes signs and symptoms described by the mnemonics SLUDGE or DUMB BELS, defined earlier.

The CNS neurotoxic effects include restlessness, agitation, lethargy, confusion, slurred speech, seizures, coma, cardiorespiratory depression, or death.

Stimulation or paralysis of nicotinic receptors at the neuromuscular junction causes muscle fasciculations, cramping, weakness, and respiratory muscle paralysis; stimulation of

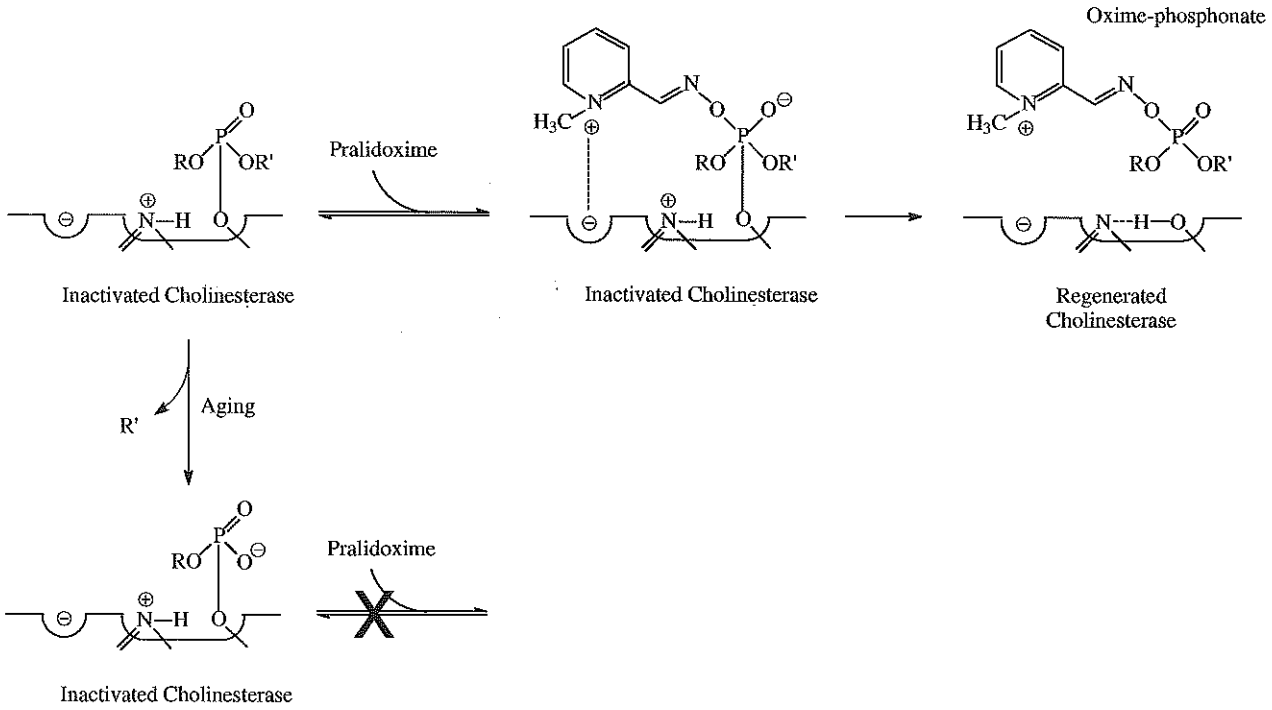

Figure 34-18 Reactivation of phosphorylated acetylcholinesterase by pralidoxime; formation of "aged" phosphorylated enzyme, which does not reactivate. The active site catalytic triad of serine, histidine, and glutamate is depicted by —OH, =NH—, and a negative charge, respectively.

nicotinic receptors at sympathetic ganglia results in hypertension, tachycardia, pallor, and mydriasis.

The actual signs and symptoms observed depend on the balance of muscarinic and nicotinic receptor activation. While miosis (muscarinic action) is most common, it may not always be present, and indeed mydriasis (nicotinic action) may occur. Likewise tachycardia (nicotinic effect) may be present rather than bradycardia (muscarinic action). Death most commonly results from respiratory failure, a consequence of nicotinic receptor–mediated muscle paralysis, combined with muscarinic-facilitated bronchorrhea, bronchoconstriction, and CNS depression.

Specific therapy for organophosphate and carbamate insecticide poisoning includes the administration of atropine (see Figure 34-15) to block the muscarinic (but not nicotinic) actions of acetylcholine. In addition, pralidoxime is given to reactivate cholinesterase. Pralidoxime binds to the cholinesterase catalytic site and via nucleophilic attack by its oxime group, dephosphorylates or decarbamylates the serine group (Figure 34-18). Pralidoxime is ineffective in reactivating the "aged" form of the phosphorylated enzyme. The administration of pralidoxime may not be necessary in cases of carbamate insecticide poisoning because carbamylated cholinesterase spontaneously reactivates within a few hours. In fact, pralidoxime is considered contraindicated in these cases by some authors, because cholinesterase inhibition by carbaryl (Sevin), but not other carbamates, may be enhanced by pralidoxime. Others administer pralidoxime in either case, because the particular insecticide ingested may not be known.[78,92] A more potent bisquaternary oxime, obidoxime, is available outside the United States.

Three neurological sequelae of organophosphate poisoning may occur after the initial cholinergic crisis has responded to atropine and oxime therapy. In what is referred to as intermediate syndrome,[403] paralysis of proximal limb muscles, neck flexors, cranial nerves, and respiratory muscles may occur 24 to 96 hours following cholinergic resolution. Respiratory muscle paralysis may be severe enough to result in death. This phenomenon, caused by excessive nicotinic receptor stimulation, may result from redistribution of lipophilic organophosphates from adipose tissue and/or from inadequate oxime therapy. In another syndrome, organophosphate-induced delayed neuropathy (OPIDN),[1] weakness of extremities, ataxia, and eventually paralysis may occur 1 to 3 weeks following severe intoxication. Respiratory muscles are not affected. It is believed that this peripheral neuropathy is the consequence of phosphorylation and inhibition of an axonal-membrane enzyme that is designated neuropathy target esterase. Alternatively, phosphorylation and activation of a Ca^{2+}/calmodulin kinase may in turn enhance proteolysis of neuronal cytoskeletal proteins and cause structural changes in neurofilaments, resulting in impaired axonal transport.[1] Finally, extrapyramidal symptoms similar to Parkinson's disease have very rarely occurred several days after cholinergic crisis resolution. A favorable response was observed with an antiparkinsonian agent.[14]

Acetylcholinesterase similar to that in nerve tissue is also present in erythrocytes, and its measurement is useful for the

diagnosis of organophosphate or carbamate insecticide poisoning (see Chapter 21). A different cholinesterase, butyrylcholinesterase (pseudocholinesterase), is present in serum and is also inhibited by these insecticides. The activity of butyrylcholinesterase declines and returns to normal more rapidly than that for the red cell enzyme.

Butyrylcholinesterase is synthesized in the liver, and its serum activity is influenced by liver disease and other acute or chronic illness. Thus red cell cholinesterase activity theoretically should correlate more closely with the degree of neurotoxicity. In acute poisoning, symptoms generally begin when cholinesterase activity is inhibited by about 50% of the lower limits of normal and this degree of inhibition is of diagnostic value. However, the degree of cholinesterase inhibition generally does not correlate well with the clinical severity of poisoning. Interpretation of test results is made more difficult because of considerable individual variability of normal levels.

Measurement of serum butyrylcholinesterase activity is easier to perform than that for red cell cholinesterase and thus is more likely to be performed in hospital clinical laboratories (see Chapter 21). These measurements are useful for the diagnosis of acute ingestions or for monitoring chronic exposure. They may be less useful in instances of carbamate insecticide poisoning because of spontaneous enzyme activity regeneration. Therapy for acute ingestion is guided by history and clinical presentation, not by cholinesterase activity. However, monitoring serum butyrylcholinesterase activity may have prognostic value in organophosphate poisoning.[15] The most definitive means of determining organophosphate or carbamate insecticide exposure is by measurement of their urinary metabolites, generally by GC-MS[379] or GC-MS-MS.[62] Such determination is not necessary nor generally available for emergency management of acutely poisoned patients.

Drugs of Abuse

Drug use and abuse are widespread in society, and public awareness has been heightened as to their impact on public safety and on lost productivity in industry. To resolve these issues, governmental, industrial, educational, and sports agencies are increasingly requiring drug testing of prospective and existing employees, students, and participants in professional and amateur athletics. Moreover, drug abuse during pregnancy is of concern, both medically and socially. Testing for drugs of abuse may also be a medical requirement for (1) organ transplantation candidates, (2) pain management clinics, (3) drug abuse treatment programs, and (4) psychiatric programs.[358] Drug testing for these purposes represents a significant activity for toxicology laboratories.

Testing for drugs of abuse usually involves testing a single urine specimen for a number of drugs. It should be noted, however, that a single urine drug test detects only fairly recent drug use; it cannot differentiate casual use from chronic drug abuse. The latter requires sequential drug testing and clinical evaluation. Moreover, urine drug testing cannot determine degree of impairment, the dose of drug taken, or the exact time of use. Many of these issues were described in detail at the 1987 Arnold O. Beckman Conference[126] and in a report by the Committee on Substance Abuse Testing.[258] Because of these and other limitations of testing for drugs in urine, there is growing interest in the use of alternate biological specimens for drug testing (see section on Alternate Specimens).

Drug testing results for nonmedical purposes may be the sole evidence for punitive action or denial of individual rights. Therefore this testing should be considered a forensic toxicology activity, requiring the highest standards of analytical methodology, specimen security, and documentation. Moreover, laboratories engaged in this testing should be appropriately certified by the Substance Abuse and Mental Health Service Administration (SAMHSA)* of the U.S. Department of Health and Human Services or the Forensic Urine Drug Testing program sponsored jointly by the American Association for Clinical Chemistry and the College of American Pathologists.

Several techniques are used during the collection of a urine specimen or subsequently in the laboratory to guard against attempts by a donor to alter the specimen in a manner that may prevent drug detection. These tactics may include the exchange of urine from a drug-free individual, or dilution of the specimen to below cutoff limits with tap or toilet water, by excessive consumption of water, or by use of a diuretic. Also, readily available adulterants, such as detergent, bleach, salt, alkali, ammonia, or acid, may be added to the specimen in an attempt to interfere with immunoassay screening procedures. Other more sophisticated adulterants specifically marketed to avoid drug detection include glutaraldehyde (Urine Aid; Clear Choice), nitrite (Klear; Whizzies), chromate (Urine Luck; Sweet Pee's Spoiler), and a combination of peroxide and peroxidase (Stealth). These adulterants also interfere with immunoassays to variable degrees and the oxidizing agents (nitrite, chromate, and peroxide/peroxidase) may result in destruction of morphine, codeine, and the principal metabolite resulting from marijuana use, thus interfering with their GC-MS confirmation as well as immunoassays.†

Direct observation of urine collection is the most stringent means to guard against specimen exchange or adulteration. However, an individual's right to privacy and dignity must be weighed against the need for the highest degree of certainty of specimen integrity. Alternative measures to prevent specimen adulteration include a (1) limitation on clothing or other personal belongings allowed in the specimen collection area, (2) addition of coloring agent to toilet water, and (3) inactivation of the hot water tap. In addition, a number of validity checks for specimen integrity may be made at the collection site and at the testing site. Validity testing criteria have been established by the DHHS for the

drug testing program mandated for U.S. federal employees.[432] According to these criteria, the specimen must be examined for unusual color, odor, foaming, or precipitate and its temperature should be 90 °F to 100 °F (32 °C to 38 °C) when determined within 4 minutes of collection. A specimen is reported as dilute when the specific gravity is >1.0010 but <1.0030 and the creatinine >2 mg/dL but ≤20 mg/dL. Although specimen recollection is not mandated, the employer may require direct observation of the next regular urine collection. A substituted specimen is defined by a specific gravity ≤1.0010 or ≥1.0200 and creatinine <2 mg/dL, whereas an adulterated urine is one with pH <3 or ≥11, nitrite >500 µg/mL (much lower concentrations occur with some urinary tract infections), or if a specific adulterant is detected and confirmed. A specimen is invalid if the pH is ≥ 3 < 4.5 or ≥ 9 < 11, if the creatinine and specific gravity are inconsistent, if nitrite is ≥ 200 < 500 µg/mL, or if the presence of other adulterants is suspected. In such cases, the urine specimen is rejected and generally not tested for drugs. The finding of a substituted or an adulterated specimen is deemed equivalent to a refusal to test and would result in the removal of the individual from safety-sensitive duties. Commercial reagents for validity testing are available in both test strip and liquid form (Table 34-7).

The urine should be collected in tamper-proof specimen cups, and a chain of custody maintained to identify all individuals involved in specimen collection, transfer, and testing. Specimens that test positive should be stored frozen for a minimum of 1 year. Detailed information on the collection and processing of specimens for drug testing has been described in the federal rules for employee drug testing[432,433] and in the federal regulations promulgated by the Department of Transportation[4] and the Nuclear Regulatory Commission.[206]

Workplace drug testing generally is restricted to alcohol (see section on alcohols) and a few drugs that have a high abuse potential, some of which are illicit. Depending on the nature of the testing program, this may involve testing for a select number of the following drugs or drug classes:

Amphetamine/methamphetamine
Barbiturates
Benzodiazepines
Cannabinoids
Cocaine
LSD
Methylenedioxyamphetamine (MDA)
Methylenedioxymethamphetamine (MDMA)
Methylenedioxyethylamphetamine (MDEA)
Methadone
Opiates
PCP
Propoxyphene

Drugs given in italics are included in a panel for testing employees of the U.S. government.[432] This panel is also used in many other testing programs and because of their widespread use is known as the "NIDA five."

Testing programs for participants engaged in athletic competition are typically much more extensive and include assays for a larger group of drugs, including stimulants, β-blockers, diuretics, and anabolic steroids. A listing of the banned drugs included in the Olympic testing programs can be found on the Canadian Center for Ethics in Sports web page (http://www.cces.ca).

Initial screening tests for the previously listed drugs are typically immunoassays (e.g., EMIT, FPIA, CEDIA, microparticle immunoassay, and RIA; see Chapter 9). These assays are calibrated at established cutoff concentrations. Specimens yielding responses greater than the cutoff (threshold) value are considered positive, whereas values below the cutoff are considered negative. Cutoff values are not synonymous with assay detection limits. Instead the

cutoff is established higher than the detection limit (to ensure reliable measurement) but low enough to detect drug use within a reasonable time frame.

Immunoassays may not be specific for the tested drug. Similar drugs may result in a positive test; for example, pseudoephedrine, present in cold medications, may produce a positive response in immunoassays designed to detect amphetamine and methamphetamine. Therefore it is imperative that positive screening tests be confirmed by an alternate, more definitive test. The most widely accepted method for drug confirmation is GC-MS. For further discussion of this technique, the reader is referred to Chapter 7. Liquid chromatography-tandem mass spectrometry is also used for rapid detection of drugs of abuse.[60,331,472]

For confirmation, quantitative drug measurements are performed using selective ion monitoring with GC-MS. Cutoff values for confirmation are established at or generally below cutoff values for the initial screening tests (Table 34-8; also see Table 34-9 for newly proposed cutoff values). The result may be reported as positive or negative relative to the cutoff value. However, the actual concentration may be helpful when interpreting morphine and codeine results (discussed later in this chapter) and when monitoring individuals enrolled in drug treatment programs. In the latter case, subjects who test positive but who have decreasing values on sequential testing may be judged abstinent, whereas those whose values suddenly increase are likely noncompliant. For this purpose, it is essential to normalize the drug concentration to urine creatinine level (nanograms of drug per milligram of creatinine). This will help compensate for fluctuations in absolute drug concentration related to physiological variation in urine dilution or concentration.[47,294]

In the following sections, the pharmacological and analytical aspects of commonly measured drugs will be discussed. Several different extraction and derivatization procedures have been used for confirmation of these drugs by GC-MS. Several of these methods are briefly described below and in more detail on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

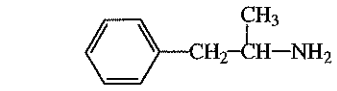
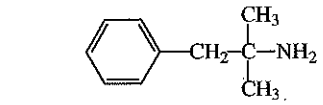
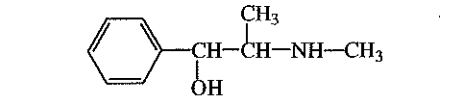
[a]Δ^9-THC-COOH.
[b]Parent and metabolite.
[c]Initial test for 6-AM allowed at cutoffs of 10 ng/mL (urine), 4 ng/mL (oral fluid), 25 ng/patch (sweat), and 200 pg/mg (hair).
[d]S(+)-methamphetamine calibrator.
[e]Cocaine ≥ cutoff and BE/cocaine ≥0.05 or cocaethylene ≥50 pg/mg or norcocaine ≥50 pg/mg.
[f]Cocaine or BE.
[g]May be reported alone if initial and confirmatory tests are above cutoffs.
[h]Must contain morphine ≥200 ng/mg.
[i]Must contain amphetamine ≥100 ng/mL.
[j]Must contain amphetamine ≥ limit of detection (LOD).
[k]Must contain amphetamine ≥50 ng/mg.



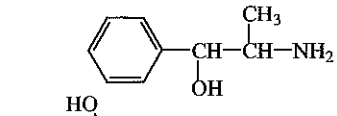
Amphetamine, Methamphetamine, and Related Sympathomimetic Amines



Amphetamine and methamphetamine (Figure 34-19) are CNS stimulant drugs that have limited legitimate pharmacological use.[201] They are used to treat narcolepsy, obesity, and attention-deficit hyperactivity disorders. However, they produce an initial euphoria and have a high abuse potential. Other sympathomimetic amines that also have high potential for abuse include the "designer" amphetamines, ephedrine, pseudoephedrine, phenylpropanolamine, and methylphenidate (Ritalin).



Pharmacological Response



Amphetamine and Methamphetamine. These drugs are sympathomimetic amines that have a stimulating effect on both the central and peripheral nervous systems. They (1) increase blood pressure, heart rate, body temperature, and motor activity, (2) relax bronchial muscle, and (3) depress the appetite. Abuse of these drugs may lead to strong psychic dependence, marked tolerance, and mild physical dependence associated with tachycardia, increased blood pressure, restlessness, irritability, insomnia, personality changes, and the severe form of chronic intoxication psychosis similar to schizophrenia. These unpleasant responses reinforce the repetitive use of the drugs to maintain the "high." In extreme cases, addicts may have "speed runs," in which large intravenous (IV) doses are used for several days during which they do not sleep or eat. This is followed, when exhaustion intervenes, by prolonged sleep for 1 or more days after which they awaken hungry but depressed, leading to repetition of the cycle.[2] Tolerance and psychological dependence develop with repeated use of amphetamines.[201] Long-

term effects may include depression and impaired memory and motor skills, probably caused by a decrease in dopamine transporters and by damage to dopaminergic and serotonergic neurons (see below).

The CNS stimulatory effects of amphetamine and methamphetamine result from their ability to enhance presynaptic release of the neurotransmitter catecholamines norepinephrine and dopamine at low to moderate dose and of serotonin at high dose and to a lesser degree to inhibit their neuronal reuptake.[201] Consequently the neurotransmitter content in the synaptic cleft is increased, resulting in enhanced postsynaptic activation. The CNS effects of norepinephrine are less well understood compared with its peripheral manifestation, but it is believed to contribute to increased mental alertness, lack of fatigue, and an anorectic effect. Dopamine regulates feeling of pleasure, emotion, motivation, and movement. It is thought to be responsible for the euphoria associated with amphetamine use. Excessive dopaminergic activity may produce acute choreoathetosis (random involuntary muscle movements) and paranoid psychosis. Serotonin modulates mood, emotion, sleep, cognition, appetite, pain sensation, temperature regulation, motor activity, sensory perception, sexual behavior, and pituitary release of antidiuretic hormone (ADH). Excessive serotonergic stimulation may lead to what is referred to as the serotonin syndrome. Symptoms of the serotonin syndrome include shivering, myoclonus (muscle spasm), muscle rigidity, tremor, hyperthermia, tachycardia, diaphoresis, hypertension progressing to hypotension, agitation, seizures, and coma. If untreated, lactic acidosis, rhabdomyolysis, myoglobinuria, acute renal failure, hepatic failure, and adult respiratory syndrome may ensue. Excessive activation of serotonergic neurons is a prominent feature of most hallucinogenic drugs (e.g., MDMA, LSD, PCP). Peripheral adrenergic activation may result in increased blood pressure, cardiac arrhythmias, diaphoresis, and mydriasis.

The optical isomers of amphetamine and methamphetamine exhibit stereoselective pharmacological properties. The CNS activity of S(+)-amphetamine is three to four times greater than of R(−)-amphetamine, but the latter drug has more potent cardiovascular effects than the former.[201] Moreover, amphetamine is metabolized primarily by oxidative deamination, a process that is stereoselective for S(+)-amphetamine.[73] Consequently, the elimination half-life for R(−)-amphetamine may be as much as 40% longer than that for S(+)-amphetamine.[468] In addition to hepatic metabolism, amphetamine is eliminated as unchanged drug in urine; the extent of such elimination is dependent on urine pH. Normally, about 30% of a dose is excreted unchanged, but this may vary from as much as 70% in acid urine to as low as 1% in alkaline urine.[26] The elimination half-life (renal excretion and hepatic metabolism) also varies with urine pH from 7 to 14 hours at acid pH to 18 to 34 hours at alkaline pH.[157] These effects of urine pH on the elimination of unchanged amphetamines are a consequence of tubular reabsorption of nonionized but not ionized amphetamine (pK_a 9.9).

The CNS effects of S(+)-methamphetamine are about 10 times greater than those of R(−)-methamphetamine, but the latter drug has greater vasoconstrictive properties than the former.[152,201] Because of the minimal CNS activity and thus low abuse potential, R(−)-methamphetamine is included in some nonprescription nasal inhalants (e.g., Vick's) for its vasoconstrictive properties.

A significant portion of a methamphetamine dose is eliminated unchanged in urine in a pH-dependent manner similar to that for amphetamine. In addition, methamphetamine is metabolized in liver primarily by hydroxylation and, to a lesser extent, by *N*-demethylation to amphetamine. Following methamphetamine ingestion, amphetamine is present in urine at a concentration that is roughly 10% of that for methamphetamine. The overall metabolism, including formation of amphetamine, is to some degree enantioselective for S(+)-methamphetamine.[46,73] Thus when racemic methamphetamine is ingested, urine specimens contain relatively more R(−)-methamphetamine than S(+)-methamphetamine, but a greater amount of S(+)-amphetamine than R(−)-amphetamine (Figure 34-20).[96,203]

Recreational use of methamphetamine and amphetamine congeners (so-called "designer" amphetamines) has had a resurgence in popularity, especially among young people who participate in all night dance parties called "raves" and in nightclubs.[11,447] At these events, loud, high-tempo "techno" music is played with a variety of strobe-type or other light effects and pyrotechnic displays. Various drugs, referred to as "club drugs," are commonly used at these events to enhance energy for prolonged partying and/or dancing (e.g., all night), to distort or enhance the visual and auditory sensations, and to promote social and physical interactions. The moniker "club drug" does not imply that recreational use is restricted to this social environment.

Designer Amphetamines. MDMA (3,4-methylenedioxymethamphetamine) is the most popular of the amphetamine-like "club drugs" and is known as ecstasy (Figure 34-19). Other "designer" amphetamines include 3,4-methylenedioxyethylamphetamine (MDEA; "Eve"), 3,4-methylenedioxyamphetamine (MDA), which is also a

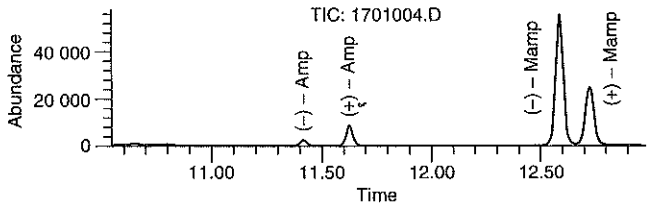

Figure 34-20 Chromatographic separation of amphetamine and methamphetamine stereoisomers after their reaction with R(−)-α-methoxy-α-trifluoromethyl-phenylacetyl chloride to form corresponding diastereoisomers. (−)-Amp and (+)-Amp, R(−)-, and S(+)-amphetamine, respectively. (−)-Mamp and (+)-Mamp, R(−)-, and S(+)-methamphetamine, respectively. This urine specimen is from an individual believed to have ingested racemic methamphetamine.

metabolite of MDMA; and 4-bromo-2,5-dimethoxyphenylethylamine (Nexus; 2 C-B).[172] Paramethoxyamphetamine (PMA) is an especially toxic designer amphetamine, which has resulted in several deaths from its unsuspected ingestion as an ecstasy substitute.[251]

MDMA has structural features in common with methamphetamine and the protypical hallucinogenic agent, mescaline (Figure 34-19), which is derived from the peyote cactus. MDMA produces a greater presynaptic release of serotonin than norepinephrine or dopamine. Consequently, it has considerably less CNS stimulant activity but greater hallucinogenic properties compared with methamphetamine. MDMA produces euphoria, enhanced pleasure and sociability, and heightened sensual arousal. Adverse effects include confusion, ataxia, restlessness, poor concentration, and psychoses. At higher doses, central and peripheral adrenergic responses similar to those described for amphetamine/methamphetamine ensue. Long-term consequences of its abuse include changes in mood, sleep disturbance, anxiety, and impairment in cognition and memory. These neuropsychiatric manifestations are a likely consequence of permanent damage to serotonergic neurons. Because of their popularity, abuse potential, and serious short- and long-term toxicity, SAMHSA has proposed to include MDA, MDMA, and MDEA in the mandatory federal workplace drug testing program.[432]

MDMA is a chiral compound in which the S(+)-enantiomer possesses the greater pharmacological activity. MDMA undergoes stereoselective demethylation to MDA, with the rate of conversion of S(+)-MDMA to S(+)-MDA exceeding that for R(−)-MDMA to R(−)-MDA. Consequently, the concentrations in urine of R(−)-MDMA and S(+)-MDA are greater than those for S(+)-MDMA and R(−)-MDA subsequent to ingestion of racemic MDMA.[148,197]

In overdose, the toxic manifestations of amphetamine, methamphetamine, and MDMA have features of adrenergic excess and the serotonin syndrome. These symptoms include dizziness, tremor, irritability, hypertension progressing to hypotension, diaphoresis, mydriasis, cardiac arrhythmias, muscle rigidity, and if severe, hyperthermia, seizures, coma, and cerebral hemorrhage.[82,201] Agitation, muscle rigidity, hyperthermia, and diaphoresis, in combination, may lead to life-threatening dehydration and rhabdomyolysis with subsequent lactic acidosis, acute renal failure, and disseminated intravascular coagulopathy (DIC). Death most commonly results from hyperthermia, dysrhythmias, and cerebral hemorrhage. Dance club participants who ingest methamphetamine or MDMA are at increased risk of severe dehydration, rhabdomyolysis, and renal failure as a result of the intense physical exertion, hyperthermia, and excessive sweating. To guard against these toxic manifestations, these individuals ingest copious amounts of water, which combined with sodium loss in sweat and stimulation of ADH release by serotonin, especially in the case of MDMA, may result in profound hyponatremia with the potential to cause cerebral edema and seizures.

Treatment for sympathomimetic amine overdose involves general supportive measures. Acid diuresis will enhance the elimination of the amphetamines, but its use is controversial[91,185] and is certainly not without the risk of renal failure from precipitation of myoglobin (enhanced at acid pH) in renal tubules (myoglobinuria is the result of rhabdomyolysis).

Ephedrine and Pseudoephedrine. These amines are diastereoisomeric adrenergic agonists. Ephedrine causes more prominent bronchodilation (β-adrenergic action) than pseudoephedrine and is present in some nonprescription medications for the treatment of asthma. Many dietary supplements contain ephedra, the herbal form of ephedrine. These products are widely marketed for weight loss and are also used by some athletes who believe they enhance performance. Ephedra, containing pills have been sold as a safe "herbal ecstasy." Adverse effects of ephedrine and ephedra include elevated blood pressure, palpitations, agitation, psychiatric disturbances, myocardial infarction, seizures, cerebral hemorrhage, and death.[405] Adverse reactions are more likely with high dose, when co-ingested with caffeine or other stimulant drugs, or with preexisting cardiovascular disease or seizure disorders. A ban on ephedra sales has been instituted in the United States; it is also banned for athletic competition by the National Football League, the National Collegiate Athletic Association, and the International Olympic Committee.

Pseudoephedrine is used for its vasoconstrictive properties (α-adrenergic action) as a nasal decongestant in a wide variety of cold remedies. Both 1R,1S(−)-ephedrine and 1S,1S(+)-pseudoephedrine have been popular starting products for the synthesis of S(+)-methamphetamine.[282] Because of this, the quantity per purchase of products containing these drugs is now restricted.

Phenylpropanolamine (PPA). Until recently, PPA was widely available in a number of nonprescription cold medications and diet control products. Adverse effects are similar to those described for ephedrine. In response to an FDA warning of increased risk of hemorrhagic stroke, especially in women, PPA has been withdrawn from the market by most manufacturers. Before this withdrawal, PPA was another popular starting product for synthesis of S(+)-methamphetamine.[282] PPA is also a metabolite of ephedrine and pseudoephedrine.

Methylphenidate (Ritalin). Ritalin is a sympathomimetic agent with psychostimulant properties similar to S(+)-amphetamine. It is widely used to treat attention deficit hyperactivity disorder (ADHD) in children and adults. There has been increasing diversion and abuse of methylphenidate among children and adults for its stimulant and purported aphrodisiac properties. In overdose, the clinical effects of methylphenidate are similar to those of amphetamine. Relatively few cases of serious overdose have been reported.

Methylphenidate is rapidly metabolized to ritalinic acid (Figure 34-21), which accounts for 60% to 89% of a dose

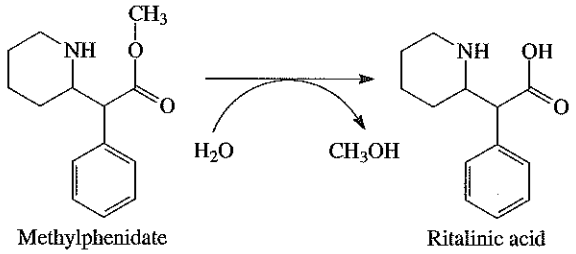

Figure 34-21 Metabolism of methylphenidate.

excreted in 24 hours. Less than 1% of the dose is excreted as the parent drug.[34]

The detection of methylphenidate compliance or abuse by urine drug assay is problematic, a phenomenon that may foster its abuse among individuals who are subjected to urine drug testing. Detection of the parent drug is made difficult by its generally low concentration, and ritalinic acid, present in much higher concentration, is difficult to extract and analyze by gas chromatographic techniques. It does not form a stable N,O-di-trimethylsilyl derivative, a probable consequence of the general instability of N-trimethylsilyl derivatives and the spatial proximity of the —NH and —COOH groups (Figure 34-21). Ritalinic acid may be analyzed directly by LC-tandem mass spectrometry,[134] or by GC-MS after sequential reactions with MSTFA and MBTFA to form the N-trifluoroacetyl,O-trimethylsilyl ester[134] or after methylation to re-form methylphenidate. Ritalinic acid may be isolated from urine using a dehydration procedure then methylated with dimethylformamide dimethyl acetal and the resulting methylphenidate analyzed by GC-MS.

Analytical Methodology[406]

The initial screening test for amphetamine and methamphetamine is typically immunoassay. For confirmation of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.

Immunoassay. Immunoassays for amphetamine and methamphetamine have variable cross-reactivities with other sympathomimetic amines, such as ephedrine, pseudoephedrine, phenylpropanolamine, phentermine, methylenedioxyamphetamine (MDA), methylenedioxyethylamphetamine (MDEA), and methylenedioxymethamphetamine (MDMA) (see Figure 34-19). Many immunoassays are less reactive with MDA, MDMA, and MDEA compared with amphetamine and methamphetamine. A multiplex CEDIA assay has been introduced that employs a combination of separate monoclonal antibodies to amphetamine, methamphetamine, and MDMA.[285] At the proposed new SAMHSA screening cutoff of 500 ng/mL (Table 34-9), this assay has good sensitivity and specificity for these drugs compared with GC-MS. A single assay for MDMA based on enzyme multiplied immunoassay technology (DRI reagent) is also available along with on-site, single use test devices (see section on On-Site Drug Testing). False-positive results, due to the phenothiazine drugs chlorpromazine and promethazine, have been reported using the EMIT assay[421]; chloroquine produced false-positive response with CEDIA amphetamine reagent.[284] For forensic application, confirmation of immunoassay positive test results by GC-MS is mandatory. Liquid chromatography-tandem mass spectrometry is applicable for sensitive and specific direct detection of MDMA and MDA in urine.[331]

Chiral discrimination of methamphetamine isomers may be necessary to distinguish use of nonprescription nasal inhalants (R[−]-methamphetamine) from illicit use of S(+)-methamphetamine. Some immunoassays have high specificity for S(+)-methamphetamine. However, definitive enantio-discrimination requires the use of a chiral derivatization reagent to form diastereomers of R- and S-methamphetamine, which may be resolved using conventional GC-MS (see Figure 34-20).[94,152,209] The Department of Defense requires chiral resolution of methamphetamine isomers. For the test to be considered positive for illicit methamphetamine use, S(+)-methamphetamine must be >20% of the total methamphetamine content (Table 34-8).

Several prescription drugs are metabolized to methamphetamine (and subsequently to amphetamine) or to amphetamine.[95] For instance, selegiline (Eldepryl), used to treat Parkinson's disease, is metabolized to R(−)-methamphetamine and R(−)-amphetamine. The (+)-isomer of benzphetamine (Didrex®), administered as an anorectic agent, is also metabolized to methamphetamine and amphetamine, presumably the S(+)-isomers. Chiral discrimination would rule out illicit use of methamphetamine in the case of selegiline but not benzphetamine. However, benzphetamine is a schedule III drug, so its use without a prescription is illicit. Other prescription drugs, not legally available in the United States, that are metabolized to methamphetamine (and amphetamine) include dimethylamphetamine, famprofazone, fencamine, and furfenorex; those metabolized to amphetamine include amphetaminil, clobenzorex, ethylamphetamine, fenethylline, fenproporex, mefenorex, mesocarb, and prenylamine.

Gas Chromatography-Mass Spectrometry. A positive screening result for amphetamine or methamphetamine (or MDA, MDEA, and MDMA) obtained by immunoassay is confirmed by GC-MS analysis of the urine specimen. A GC-MS method for amphetamine and methamphetamine that can be adapted to include MDA, MDMA, and MDEA is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). With this method, it should be noted that specimens containing ephedrine or pseudoephedrine occasionally have been reported to test positive for methamphetamine when 4-carbethoxyhexafluorobutyryl chloride (4-CB) is used as a derivatizing reagent.[443]

To guard against a false-positive report of methamphetamine owing to the presence of ephedrine or pseudoephedrine, SAMHSA regulations require identification of methamphetamine (cutoff, 500 ng/mL) and of its metabolite, amphetamine (cutoff, 200 ng/mL). Amphetamine-4-CB

is not formed from α-hydroxyamines. However, the requirement for amphetamine ≥200 ng/mL may not be satisfied in some cases of known methamphetamine ingestion, especially during the initial 12 hours postdose period, leading to false-negative results.[457,490] To increase detection rate for amphetamine and methamphetamine, SAMHSA has proposed[432] a reduction of the screening and confirmation cutoff from 1000 ng/mL and 500 ng/mL to 500 ng/mL and 250 ng/mL, respectively. Methamphetamine would require the presence of at least 100 ng/mL amphetamine metabolite for a positive result. In a 2002 study,[345] these lower cutoff values increased the detection rate for methamphetamine by 48% compared with current cutoff values. Moreover, the highest detection rate for methamphetamine was achieved by use of the 250 ng/mL cutoff with elimination of the amphetamine requirement. In the described procedure, periodate oxidation before derivatization destroys α-hydroxyamines and therefore eliminates possible false report of methamphetamine owing to their presence.[147]

Barbiturates

The barbiturates have a low therapeutic index and a relatively high abuse potential. Because of their rapid onset and short duration of action, the short- to intermediate-acting barbiturates are used as sedative-hypnotics (amobarbital, butabarbital, butalbital, pentobarbital, and secobarbital) and are those most commonly abused. The longer acting barbiturates (mephobarbital and phenobarbital), used primarily for their anticonvulsant properties, are rarely abused.

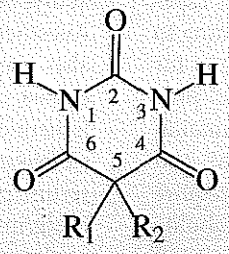
Pharmacological Response

Barbiturates suppress CNS neuronal activity and thus have sedative and hypnotic properties.[186] This CNS suppression is a result of barbiturate-enhanced activation of the inhibitory GABA-ergic neuronal system mediated by the neurotransmitter γ-aminobutyric acid (GABA).[86] Postsynatic $GABA_A$ receptors are multisubunit transmembrane Cl^- conductance channels, which when activated by GABA open to allow flow of Cl^- into the neuron, with subsequent hyperpolarization and inhibition of electrical transmission. At low dose, some barbiturates bind to the $GABA_A$ receptors and enhance their response to GABA. At a higher dose, barbiturate binding results in prolonged opening of the Cl^- channel, without the necessity for GABA binding. In addition, barbiturates suppress excitatory glutamate-responsive AMPA (alpha-amino-3-OH-4-isoxozole propionic acid) ion-gated receptor subtypes.

Because of their low therapeutic index and high potential for abuse, the barbiturates have largely been replaced by the safer benzodiazepines for sedative and hypnotic purposes. Nevertheless, they continue to be available for this purpose or in combination with other analgesic, antihypertensive, antiasthmatic, antispasmodic, or antidiuretic drugs. The combination of barbiturates, such as butalbital with analgesic preparations, is ironic. Not only do barbiturates lack analgesic properties, but at low doses they antagonize the effects of analgesics. Phenobarbital is effective as an anticonvulsant drug (see Chapter 33), and short- and ultrashort-acting barbiturates (Table 34-10) are used for IV anesthesia. Anesthetic doses of barbiturates, such as pentobarbital, are also used to reduce intracranial pressure from cerebral edema associated with head trauma, surgery, or cerebral ischemia.[295] For the induction of this therapeutic coma, sufficient pentobarbital is administered IV to achieve a serum pentobarbital concentration between about 20 and 50 μg/mL. Therefore appropriate analytical methods are necessary to monitor serum pentobarbital concentrations in these circumstances. Moreover, barbiturates continue to be subject to abuse and are a source of intentional or, less commonly, accidental drug intoxication. Measurement of the common barbiturates in serum or urine can aid in the diagnosis and management of barbiturate intoxication.

The general formula for barbiturates is given in Table 34-10. Any change in the constituents at position five that confers an increase in lipid solubility typically results in increased onset of action, decreased duration of action, and increased potency. Moreover an increase in hydrophobic properties also leads to more rapid and extensive hepatic metabolic clearance and thus to decreased urinary elimination of an unchanged drug.

The classification of barbiturates as "ultrashort-acting," "short-acting," "intermediate-acting," and "long-acting" refers to the duration of effect and not to the elimination half-life. The duration of action is determined by the rate of distribution into brain and subsequent redistribution to other tissues.[86]



The major manifestations of barbiturate intoxication are CNS, cardiovascular, and respiratory depression. Severe intoxication results in coma, hypothermia, hypotension, and cardiorespiratory arrest.

Appropriate treatment for barbiturate intoxication includes general cardiopulmonary support and measures to prevent further drug absorption and to enhance elimination. Urine alkalinization may enhance the elimination of long-acting barbiturates (e.g., phenobarbital and barbital) but has little effect on intermediate-, short-, or ultrashort-acting barbiturates.

Once filtered by the glomerulus, a nonionized drug may be appreciably reabsorbed by the tubules. The goal of alkalinization is to maintain the urine pH between 7.5 and 8.5. In this pH range, a large fraction of an acidic drug will be ionized, and its elimination in urine will thus be enhanced.

For urine alkalinization to be effective, the drug should have low plasma protein binding, be appreciably eliminated in urine as an unchanged drug, and have a pK_a below 7.4. From an examination of Table 34-10, only phenobarbital (and other long-acting barbiturates [e.g., barbital]) fulfills these criteria. The primary route of elimination of ultrashort-, short-, and intermediate-acting barbiturates is by hepatic metabolism. Thus with the exception of aprobarbital, only small amounts are eliminated in urine as an unchanged drug. Moreover, at pH 8.0, only about 50% of a

short- or intermediate-acting barbiturate (pK_a 7.9 to 8.1) is ionized, whereas phenobarbital (pK_a 7.2) is about 85% ionized. Hemodialysis is effective in increasing the elimination of all barbiturates. However, it is more effective for long-acting barbiturates than for shorter-acting barbiturates because of differences in their lipid solubility and protein binding. Whereas urine alkalinization may increase the elimination of phenobarbital somewhat, it is considerably less effective than the process referred to as GI dialysis, which is mediated by the repeated oral administration of activated charcoal (multiple-dose activated charcoal, MDAC).[9,131]

The rationale for MDAC therapy is that drug secreted into the GI tract (along with a previously unabsorbed drug) is bound by charcoal and thus cannot be reabsorbed. Drugs that are amenable to this process are ones that have a small volume of distribution, low protein binding, and a prolonged elimination $t_{1/2}$ following overdose. Currently, MDAC is recommended only for the treatment of serious phenobarbital, theophylline, carbamazepine, quinine, and dapsone overdose.[9]

The barbiturates undergo extensive hepatic metabolism in which the C5 substituents are transformed to alcohols, phenols, ketones, or carboxylic acids; these metabolites may be excreted in urine in part as glucuronide conjugates. For some barbiturates (amobarbital and phenobarbital), *N*-glucosylation is an additional important metabolic trans-

formation (Figure 34-22). As a result, only a relatively small amount of an administered barbiturate dose is excreted in urine as a parent drug; notable exceptions are phenobarbital and aprobarbital (Table 34-11). Nevertheless, the parent drugs, rather than hydroxy or carboxylic acid metabolites, are targeted for detection in urine screening and confirmation procedures. This analytical approach is generally successful for barbiturates, because these drugs are ingested in sufficiently high doses to allow detection of unmetabolized drug in urine.

Analytical Methodology

Methods are available for detecting barbiturate overdose and abuse. To detect overdose, semiquantitative immunoassays suitable for detection of barbiturates in serum are available and useful for this purpose. Capillary GC is also useful for this purpose, and a capillary GC procedure is described in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). Barbiturate overdoses are also detected in urine by TLC (e.g., Toxi-Lab) or by immunoassay. To detect barbiturate abuse by analyzing urine specimens, immunoassay and GC-MS are the methods of choice for screening and confirmation, respectively.

Immunoassay. Commercial immunoassays for barbiturates include EMIT, FPIA, Triage, DPC RIA, Abuscreen Online, Abuscreen RIA, and CEDIA. All use secobarbital as the calibrator at a cutoff concentration of either 200 or 300 ng/mL. The degree of cross-reactivity of other barbiturates varies with each assay.[281] Little information is known concerning cross-reactivity with barbiturate metabolites, except for *p*-hydroxyphenobarbital, which is detected by several of the immunoassays.[281] The detection period in urine following ingestion of barbiturates varies somewhat with different assays and depends on the pharmacological properties of the drugs. The short- to intermediate-acting barbiturates may generally be detected for 1 to 4 days following use; long-acting barbiturates, such as phenobarbital, may be detected for several weeks after chronic use.[181]

Capillary Gas Chromatography. To detect barbiturate overdose, a serum sample can be analyzed for several barbiturates using the capillary GC technique described in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). In this method, aprobarbital is first added to an aliquot of the sample as an internal standard. Barbiturates in the aliquot are then extracted twice with diethyl ether, and the ether is dehydrated with solid sodium sulfate and then evaporated to dryness. The residue is dissolved in 50 µL of ethyl acetate, and an aliquot is injected into the gas chromatograph.

Gas Chromatography-Mass Spectrometry. In practice, a positive screening result for barbiturates obtained by immunoassay is confirmed by GC-MS analysis of the urine specimen. A GC-MS method for barbiturates is included in the Chapter 34 Appendix that is found on this book's

accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

In this method, a urine specimen that tests positive for barbiturates by immunoassay is extracted (liquid-liquid). The extract is then dried and treated with *N,N*-dimethylformamide dimethyl acetal to form methyl derivatives of the barbiturates. Following addition of a buffer, the methylated barbiturates are extracted with hexane and analyzed by GC-MS. Pentobarbital-D_5 and phenobarbital-D_5 are used as internal standards for quantitation.

Benzodiazepines

Benzodiazepines are any of a group of compounds having a common molecular structure and acting similarly as depressants of the CNS.

Pharmacological Response

Benzodiazepines have anxiolytic, sedative-hypnotic, muscle relaxant, and anticonvulsant properties. They are among the most commonly prescribed drugs in the western hemisphere because of their efficacy, safety, low addiction potential, minimal side effects, and high public demand for sedative and anxiolytic agents; they have largely replaced barbiturates for sedative-hypnotic use.[86,149,288] Thirteen benzodiazepines are currently approved for use in the United States (Table 34-12). Qualitatively, they all have similar pharmacological effects. Specific clinical applications are largely determined by differences in onset and duration of action and by quantitative differences in their clinical effects. One member of this class, alprazolam, has been used for the treatment of depression. Another benzodiazepine, flunitrazepam (Figure 34-23), is approved for use in many countries but not the United States. However, it has illegally entered the United States (especially Texas and Florida) and has been illicitly sold to the drug-abusing community. In addition, because of its potent sedative-hypnotic action, especially in combination with alcohol, and its ability to induce short-term amnesia, it has gained notoriety as a "date rape" pill.

Benzodiazepines are typically administered orally, and the rate of absorption is the principal determinant of the rate of onset and the intensity of action. Highly lipophilic benzodiazepines (diazepam and flurazepam) are rapidly absorbed (time to peak serum concentration <1.2 hours), and less lipophilic compounds (oxazepam and temazepam) are more

TABLE 34-12 Benzodiazepine Characteristics

Compound (Trade Name)	Therapeutic Uses	$t_{1/2}$ (hr)	Main Urinary Metabolite
Alprazolam (Xanax)	Anxiety; depression	8-14	α-hydroxy glucuronide
Chlordiazepoxide (Librium, others)	Anxiety; alcohol withdrawal; preanesthetic medication	6-27; active metabolites	Oxazepam glucuronide
Clorazepate (Tranxene, others)	Anxiety; seizure disorders	2 (prodrug)* active metabolite	Oxazepam glucuronide
Diazepam (Valium, others)	Anxiety; status epilepticus, muscle relaxation; preanesthetic medication	30-56	Oxazepam glucuronide
Lorazepam (Ativan)	Anxiety; preanesthetic medication	8-25	Lorazepam glucuronide
Oxazepam (Serax)	Anxiety	5-15	Oxazepam glucuronide
Estazolam (Prosom)	Insomnia	10-24	4-hydroxy glucuronide
Flurazepam† (Dalmane)	Insomnia	2-3; active metabolite, 50-100	N^1-hydroxy ethyl glucuronide
Quazepam (Doral)	Insomnia	6-10	2-oxo-3-hydroxy glucuronide
Temazepam (Restoril)	Insomnia	5-17	Temazepam glucuronide
Triazolam (Halcion)	Insomnia	2-3	α-hydroxy glucuronide
Clonazepam (Klonopin)	Seizure disorders	20-60	7-amino-3-hydroxy conjugates
Midazolam (Versed)	Preanesthetic and intraoperative medication	1-4	α-hydroxy glucuronide

slowly absorbed (time to peak serum concentration 2 to 3 hours).[86,149]

Following GI absorption or IV administration, benzodiazepines are rapidly distributed to the CNS. Subsequently, benzodiazepines are more slowly redistributed from the CNS to more poorly perfused tissue, such as adipose tissue and muscle. The rate of this redistribution is an important determinant of the duration of action of benzodiazepines and, like that for GI absorption, is largely determined by drug lipophilicity, with the more lipophilic drugs, such as midazolam and triazolam, having the shortest duration of action. Additional factors that influence the duration of benzodiazepine action are hepatic metabolism and acute tolerance, resulting in decreased response to benzodiazepines with continued drug exposure.

Benzodiazepines undergo hepatic oxidation and conjugation, often forming metabolites with pharmacological activity (Figures 34-23 through 34-27). Several benzodiazepines are metabolized to oxazepam, which is then excreted as the inactive glucuronide. Others are inactivated by glucuronidation as the only (lorazepam) or most important (temazepam) metabolic transformation. In some cases, metabolic transformations occur before the drug reaches significant concentrations in the systemic circulation. For example, clorazepate is decarboxylated to nordiazepam by stomach acid, and flurazepam and prazepam are converted to active metabolites by hepatic first-pass metabolism.[86,149]

Benzodiazepines with the shortest elimination half-life ($t_{1/2}$) generally have the shortest duration of action. In some cases, an active metabolite may have a $t_{1/2}$ longer than the parent drug and thus contributes to a longer duration of action. For instance, flurazepam has a $t_{1/2}$ of 2 to 3 hours, but its active metabolite, desalkylflurazepam, has a $t_{1/2}$ of 50 to 100 hours. These pharmacokinetic properties in part determine the primary clinical applications for some benzodiazepines. For instance midazolam ($t_{1/2}$ = 1 to 4 hours) is used for preanesthetic sedation or for sedation for endoscopic procedures because of its rapid onset and short duration of action.

Benzodiazepines useful to treat anxiety generally have an intermediate to long elimination $t_{1/2}$ (alprazolam and diazepam), and those primarily used as anticonvulsants (clonazepam) have a long $t_{1/2}$. Elimination $t_{1/2}$ is clearly not the sole determinant of duration of action of benzodiazepines. In some cases, the rate of drug redistribution from the CNS may be an even more important factor. For instance, midazolam ($t_{1/2}$ = 1 to 4 hours) and diazepam ($t_{1/2}$ = 30 to 56 hours) were demonstrated to have equivalent recovery times for single-dose, short-term sedation.[13] For this application, the distribution kinetics for diazepam are more significant than elimination $t_{1/2}$.

Benzodiazepines act on the CNS by potentiating the action of the major endogenous CNS inhibitory neurotransmitter, γ-aminobutyric acid (GABA).[86,149] Benzodiazepines bind to $GABA_A$-receptor sites and thereby enhance GABA-mediated chloride transmembrane conductance, which results in hyperpolarization and diminished neural electrical discharge. The remarkable safety of benzodiazepines compared with barbiturates is probably related to their activation of the endogenous GABA effect. Conversely, high doses of barbiturates increase neural chloride conductance independent of GABA.

Some degree of tolerance and physical dependence may develop after prolonged use of benzodiazepines.[408] A withdrawal syndrome similar to that for barbiturates and alcohol may be observed, but it is generally less severe, less frequent,

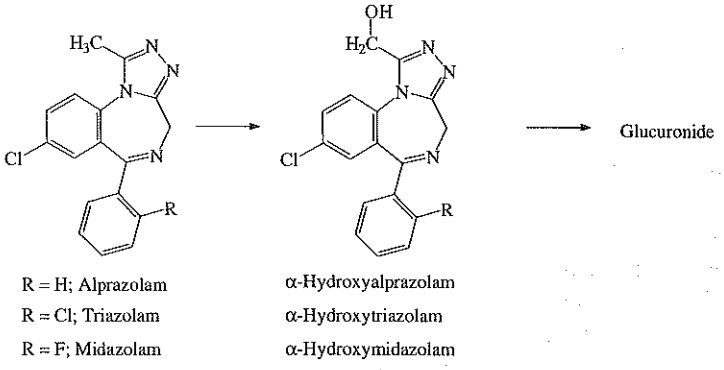

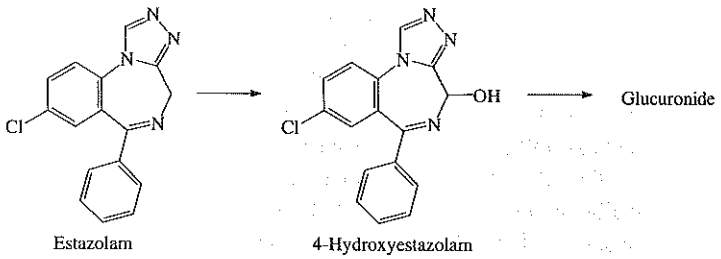

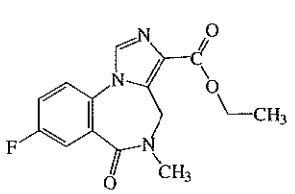

Figure 34-27 Metabolic transformation of some triazolobenzodiazepines.

and not as prolonged.[149] These symptoms may include anxiety, apprehension, tremors, muscle weakness, anorexia, nausea, vomiting, dizziness, hyperthermia, and convulsions. The frequency and severity of withdrawal symptoms are greater for the most rapidly eliminated benzodiazepines, with longer duration of therapy (>4 months), with higher doses, and with abrupt discontinuation of the drug.[149,288] Withdrawal symptoms may be especially severe for alprazolam. Tolerance to some effects of benzodiazepines may occur. Tolerance is believed to result from an adaptation of the GABA-receptors to continued benzodiazepine exposure, whereby their response is diminished. This leads to the need for higher doses to achieve the desired effect.

Despite their widespread use, abuse of benzodiazepines is relatively low and is more likely to occur in individuals who abuse other drugs or alcohol. However, as a result of their widespread use, benzodiazepine intoxication is not uncommon. Benzodiazepine CNS toxicity is generally mild to moderate and may be manifest as drowsiness, slurred speech, ataxia, and occasionally coma. More serious toxic effects causing respiratory depression or cardiovascular compromise are infrequent. Indeed, few well-documented deaths have been attributed to benzodiazepine intoxication alone.

Treatment for benzodiazepine intoxication is supportive; respiratory assistance is generally only necessary when benzodiazepines are co-ingested with other CNS depressants, such as alcohol. Because of extensive protein binding (85% to 95%) and a large volume of distribution (1 to 3 L/kg), hemodialysis or hemoperfusion is not effective. Flumazenil (Figure 34-28), a benzodiazepine antagonist, quickly improves the clinical condition in cases of benzodiazepine overdose but is probably not necessary for most cases.[204] In instances of coma secondary to multiple drug overdose, removal of the benzodiazepine contribution by flumazenil may avoid the need for intubation and ventilatory assistance. Moreover a trial dose of flumazenil may aid in the diagnosis of benzodiazepine overdose and possibly avoid other procedures, such as a computed tomography scan. Caution is needed when administering flumazenil in cases of mixed tricyclic antidepressant–benzodiazepine overdose, because adverse effects have been reported, including precipitation of seizures and cardiac arrhythmias. Therefore it may be prudent to perform a screening test for tricyclic antidepressants before administration of flumazenil. Flumazenil is not detected by immunoassays for benzodiazepines.[316]

Flumazenil

Figure 34-28 Chemical structure of flumazenil.

Analytical Methodology

Benzodiazepines may be identified and quantified in serum, generally by HPLC, but such quantitative information is not warranted in cases of benzodiazepine overdose because serum levels are not predictive of severity of intoxication.[149] However, a urine or serum immunoassay screening test for benzodiazepines is valuable to aid in the evaluation of patients with an unknown cause of CNS depression.

To detect abuse, the initial screening test for benzodiazepines is typically immunoassay. For confirmation of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.

Immunoassay. Several commercial immunoassay systems are available for the detection of a wide variety of benzodiazepines and metabolites (e.g., EMIT, Roche Abuscreen Online, FPIA, CEDIA, BioSite Triage, and DPC RIA). These immunoassays differ somewhat in their ability to detect the various benzodiazepines, their metabolites, and glucuronide conjugates. The response with the EMIT, FPIA, Online, and CEDIA assays for several benzodiazepines is enhanced by prior hydrolysis of urine with β-glucuronidase[407]; hydrolysis is most important to ensure detection of oxazepam, temazepam, nordiazepam, and lorazepam.* The CEDIA and Online methods have been adapted for automated online hydrolysis.[45,307,384] The Triage test device uses monoclonal antibodies selected for their reactivity with the benzodiazepine glucuronide conjugates; glucuronidase hydrolysis would actually decrease the test's detection limit with this device.[249] The detection time in urine following benzodiazepine use is extremely variable and depends on a number of factors, including the immunoassay system, inclusion of glucuronidase hydrolysis, the benzodiazepine ingested, the dose, and the duration of drug use. Long-acting benzodiazepines (diazepam, chlordiazepoxide, and clorazepate) are given in relatively large doses and may be detected for several days to weeks or even months following chronic use. Short-acting benzodiazepines (alprazolam and triazolam) are used in lower doses and might only be detected for a few days. The analytical specificity of benzodiazepine immunoassays is good; few false-positive results have been reported. Oxaprozin (a nonsteroidal anti-inflammatory drug) causes a positive response with the EMIT, FPIA, Triage, and CEDIA benzodiazepine assays.[329] False-negative results are common, especially when the immunoassay is performed without prior glucuronide hydrolysis. In one large study conducted in 2002,[61] the sensitivity and specificity for EMIT, compared with GC-MS, were 67% and 100%, respectively, without hydrolysis and 87% and 96%, respectively, with enzyme pretreatment.

The detection of flunitrazepam (Rohypnol) is especially challenging because of the low therapeutic and illicit doses, and the low degree of cross-reactivity of most immunoassays with the principal urinary metabolite, 7-

*References 44, 45, 61, 303, 305, 307, 384, 418.

aminoflunitrazepam.[390,423,467,469] As for other benzodiazepines, prior glucuronidase hydrolysis may improve immunoassay detection.[390] ELISA methods with high selectivity for 7-aminoflunitrazepam and improved sensitivity have been developed.[467,469] In the absence of a sufficiently sensitive immunoassay, direct analysis of 7-aminoflunitrazepam by GC-MS is indicated in suspected cases of flunitrazepam ingestion (e.g., suspected "date rape").

Gas Chromatography-Mass Spectrometry. A positive screening result for benzodiazepines obtained by immunoassay is confirmed by GC-MS analysis of the urine specimen. A GC-MS method for benzodiazepines is included in the Chapter 34 Appendix that is found on the book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Cannabinoids

Cannabinoids are a group of C_{21} compounds found in the plant species *Cannabis sativa*. The principal psychoactive cannabinoid is Δ^9-tetrahydrocannabinol (THC) (Figure 34-29). THC is typically consumed by smoking marijuana, which is a mixture of crushed leaves, flowers, and sometimes stems from the cannabis plant. Hashish, the dried, resinous secretions of the plant, may also be smoked. Hashish generally has a higher content of THC than does marijuana.

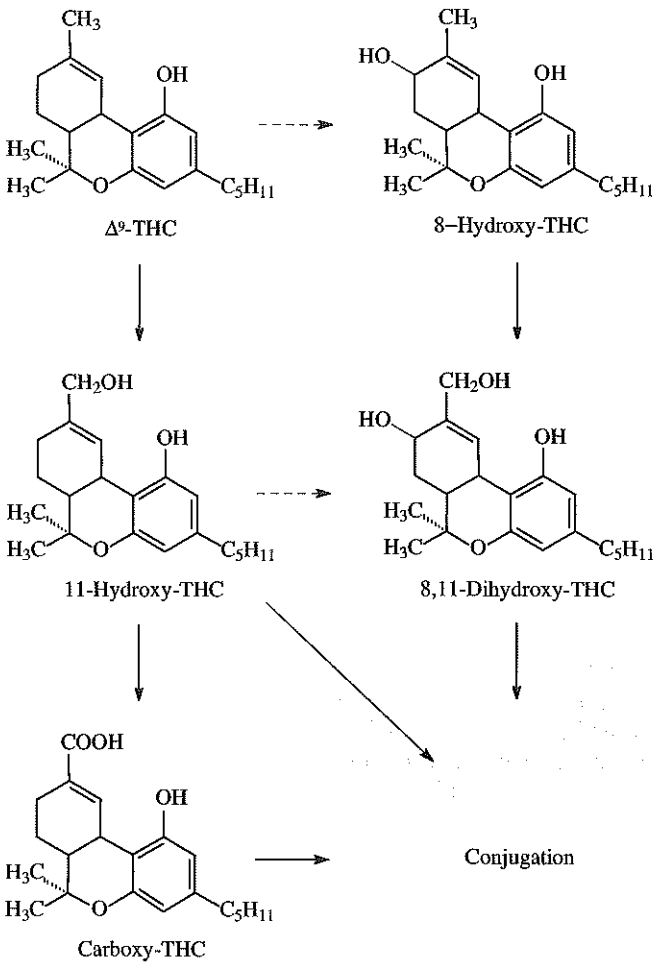

Figure 34-29 Principal metabolic route for THC in humans.

Pharmacological Response

The major psychoactive effects of THC are euphoria and a sense of relaxation and well-being. These effects occur within minutes of smoking marijuana, reach a peak in about 15 to 30 minutes, and may persist for 2 to 4 hours.[121,235] Associated with this "high" are a loss of short-term memory and impairment of intellectual performance (recall, reading comprehension, ability to concentrate, and mathematical problem solving). Moreover, psychomotor skills may be sufficiently impaired to adversely affect automobile or airplane operating performance.[235] Some controversy exists concerning the degree of impairment of performance much beyond 4 hours after marijuana use. Even greater uncertainty surrounds the long-term negative health effects of chronic marijuana use. Tolerance and a mild degree of physical dependence may develop after chronic marijuana and hashish use.

Endogenous cannabinoid receptors have been identified in brain and on B lymphocytes and macrophages.[16] They are transmembrane G-protein coupled receptors with signal transduction pathways, which involve modulation of adenyl cyclase, inhibition of voltage-dependent Ca^{2+} channels, and activation of K^+ channels. Subsequent to recognition of these receptors, two endogenous cannabimimetic eicosanoids, arachidonylethanolamide (anandamide) and 2-arachidonyl-glycerol, have been identified.[16,297] These receptors are postulated to be involved in modulation of mood, memory, cognition, movement, pain recognition, thermoregulation, appetite, and immune response.

After inhalation of marijuana smoke, THC is rapidly absorbed through the lungs and reaches peak blood concentration within minutes; thereafter, blood concentration rapidly declines to about 10% of peak levels within 1 to 2 hours. This rapid decline in THC concentration is a result of its facile distribution to tissue such as brain, fat, and muscle. The rapid tissue distribution phase, a consequence of the lipophilic nature of THC, is followed by a slow redistribution of THC back into the blood stream and subsequent hepatic elimination. The terminal elimination half-life of THC is about 1 day in casual marijuana users and 3 to 5 days in chronic users.[224,235] The peak psychoactive effects of THC generally lag behind the peak blood concentration by about 20 to 30 minutes.[121] Undoubtedly the concentration of THC in venous blood poorly reflects the THC concentration in the brain.

Although marijuana is the most frequently used illicit drug, it does have some limited legitimate medicinal use. Dronabinol (Marinol) contains synthetic THC and is used to treat anorexia and nausea in AIDS patients, nausea and vomiting associated with chemotherapy, and asthma and glaucoma.[343]

Nine U.S. states have legalized the use of marijuana for medical purposes. However, marijuana trafficking remains

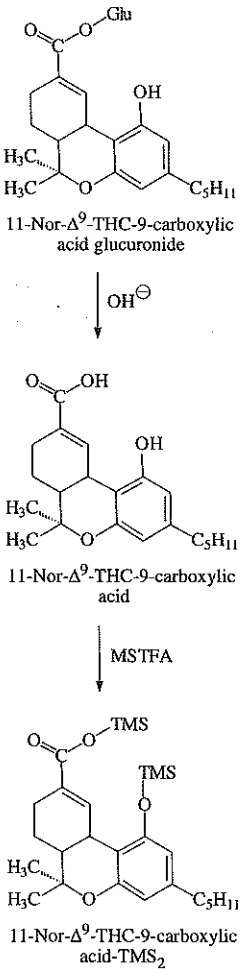

Figure 34-30 Chemical structure of derivatives of THC metabolites. *Glu,* Glucuronide.

a crime under federal law. Measurement in urine of the carboxylic acid metabolite of Δ^9-tetrahydrocannabivarin (C3 homologue of THC), present in cannabis but not in dronabinol, has been proposed as a means to distinguish ingestion of marijuana from that of Marinol.[144]

Analytical Considerations

The initial screening test for THC is typically immunoassay. For confirmation of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.

Immunoassay. THC is extensively metabolized to a large number of compounds, most of which are inactive. The principal urinary metabolite is 11-nor-Δ^9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH) and its glucuronide conjugate (see Figure 34-30). Immunoassays designed to screen urine samples for marijuana use measure this and other THC metabolites. These assays are calibrated with THC-COOH, but because of cross-reactivity with many other THC metabolites, quantitative results based on them are 1.5 to 8 times greater than the actual concentration of THC-COOH as determined by GC-MS.[226] Therefore immunoassay results are interpreted as THC-COOH equivalents.

Because of the slow release of THC from tissue storage sites, urine may test positive for THC metabolites (>20 ng/mL THC-COOH equivalents) for 2 to 5 days after last marijuana use by infrequent smokers; some individuals may test positive for as long as 10 days. Chronic smokers may test positive for 3 to 4 weeks after abstinence.[38,399] Some heavy smokers may remain positive for up to 46 days and may require as long as 77 days to test negative for 10 consecutive days.[142] Therefore, a positive urine test for THC-COOH can only be interpreted to indicate past marijuana use (immediate to several weeks) and is unrelated to impairment.

Due to fluctuations in fluid excretion, the concentration of THC metabolites in urine may suddenly increase rather than decline or may vary between positive and negative values when sequentially measured during the terminal elimination phase after abstinence. In this case, an increase in metabolite concentration could falsely imply reuse of marijuana. Therefore, to better monitor abstinence, the concentration of THC-COOH should be expressed per milligram of creatinine.[38,47,261,262] Increases of 0.5[207] and 1.5[293] in the THC-COOH to creatinine ratio between two specimens collected at least 24 hours apart have been proposed as criteria to indicate reuse. The specimen-ratio criterion of 0.5 has the higher sensitivity and would be better applied for monitoring in drug treatment programs. However, the 1.5 ratio criterion has very high specificity (low false-positive) and would be more appropriate if punitive action is anticipated.[163,207]

Legitimate concern has been raised about the possibility of "passive inhalation" of sufficient sidestream marijuana smoke from nearby users to result in a positive urine cannabinoid test. It has been demonstrated that such can occur but under rather unrealistic conditions.[102] Under more normal circumstances, passive inhalation did not result in a urine THC-COOH concentration in excess of 12 ng/mL.[102,323] Nevertheless, as a precaution against passive inhalations resulting in a positive test, some laboratories screen for urine cannabinoids at a cutoff concentration of 100 ng/mL THC-COOH equivalents. However, at this cutoff value, test sensitivity in one study was only 47% when compared with that for GC-MS (cutoff value, 15 ng/mL THC-COOH). Test sensitivity increased to 93% at a cutoff value of 20 ng/mL THC-COOH equivalents.[414] The U.S. federally mandated screening cutoff was reduced from 100 ng/mL to 50 ng/mL THC-COOH equivalents.[292] One study demonstrated that such a reduction in screening cutoff resulted in a 23% to 54% increase in test sensitivity, depending on immunoassay, with only a slight decrease (1.0% to 2.6%) in test specificity.[208] A 1997 study suggests that consideration should be given to lowering the values listed for Δ^9-THC-COOH in Table 34-8.[482]

Seeds and oil from the hemp plant (also a variety of *Cannabis sativa* L) contain Δ^9-tetrahydrocannabinol. Consumption as nutritional supplements of hemp-seed oil with

relatively high THC content may result in a positive urine test for THC-COOH,[267,431] thus prompting a "hemp defense" as explanation for the test result. Since 1998, the hemp industry has made an effort to reduce the THC content of these products by including a wash step before seed processing. Repeated daily ingestion of hemp oil with current lower THC content is not likely to result in a positive urine test for THC-COOH at SAMHSA cutoffs,[271] but it is possible.[183] In 2001, the DEA included any product that contains THC under the Schedule I controlled substance classification,[214] thus negating the "hemp defense."

Gas Chromatography-Mass Spectrometry. A positive screening result for THC obtained by immunoassay is confirmed by GC-MS analysis of the urine specimen. A GC-MS method for THC is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Cocaine

Cocaine is an alkaloid present in the leaves of the coca plant that grows in South America. The drug has a long history of human consumption, beginning with its use by ancient South American civilizations, followed by its initial incorporation in a popular cola drink (discontinued in the early 1900s), and continuing to its current popularity as a recreational drug.[179,222]

Pharmacological Response

Cocaine is a potent CNS stimulant that elicits a state of increased alertness and euphoria[179,222] with its actions similar to those of amphetamine but of shorter duration. These CNS effects are thought to be largely associated with the ability of cocaine to block dopamine reuptake at nerve synapses and thereby prolong the action of dopamine in the CNS. It is this response that leads to recreational abuse of cocaine. Cocaine also blocks the reuptake of norepinephrine at presynaptic nerve terminals; this produces a sympathomimetic response (including an increase in blood pressure, heart rate, and body temperature). Cocaine is effective as a local anesthetic and vasoconstrictor of mucous membranes and is therefore used clinically for nasal surgery, rhinoplasty, and emergency nasotracheal intubation.

For recreational use, cocaine (hydrochloride salt) is often administered by nasal insufflation ("snorting") or less frequently, intravenously. Cocaine is more volatile when converted from the salt to the freebase; therefore freebase cocaine may be inhaled by smoking. This latter route of administration results in a rapid onset of action. It has gained increased popularity owing to the ready availability of the freebase cocaine form known as "crack." Consequently the number of emergency room admissions related to cocaine toxicity has increased.[109,179]

The CNS and cardiovascular effects of cocaine exhibit acute tolerance, with its effects more pronounced when the concentration of cocaine in blood is increasing than when it is at a similar but decreasing concentration.[8,222] Thus a clockwise hysteresis is observed when the blood concentration of cocaine is plotted against its CNS or cardiovascular effects over time. This phenomenon mitigates against attempts to correlate isolated blood concentration values with psychomotor effects. Because rate of change is probably more significant than absolute concentration, the psychomotor stimulant effects of cocaine are dependent both on dose and on route of administration, with IV administration and smoking resulting in the most rapid rate of increase in concentration.

Acute cocaine toxicity produces a sympathomimetic response that may result in mydriasis, diaphoresis, hyperactive bowel sounds, tachycardia, hypertension, hyperthermia, hyperactivity, agitation, seizures, or coma. Sudden death due to cardiotoxicity may occur following cocaine use. Death may also occur following the sequential development of hyperthermia, agitated delirium, and respiratory arrest. Excited delirium and extreme physical activity may lead to rhabdomyolysis, acute renal failure, and disseminated intravascular coagulopathy.

Cocaine is rapidly hydrolyzed by separate liver esterases to the inactive metabolites ecgonine methyl ester and benzoylecgonine (Figure 34-31). Ecgonine methyl ester may also be formed by the action of serum butyrylcholinesterase, and cocaine may be converted to benzoylecgonine by spontaneous hydrolysis. The formation of benzoylecgonine has often been attributed entirely to spontaneous hydrolysis, but it has clearly been shown to be mediated mainly by a liver carboxyesterase.[116] This latter enzyme, in the presence of ethanol, catalyzes transesterification of cocaine (benzoylecgonine methyl ester) to cocaethylene (benzoylecgonine ethyl ester). Cocaethylene possesses the same CNS stimulatory activity as cocaine in experimental animals.[196] Ethanol and cocaine are commonly co-abused, and it is speculated that formation of cocaethylene may cause enhanced CNS stimulation and therefore lead to reinforcement of the co-abuse. Cocaethylene may also result in enhanced cardiotoxicity; it is more lethal than cocaine in experimental animals.[195] Cocaethylene is not infrequently present in urine or serum of hospital patients who test positive for benzoylecgonine.[18,492] When "crack" cocaine is smoked, a pyrolysis product, anhydroecgonine methyl ester, is formed and may be detected in urine.[217,346]

The elimination half-life for cocaine ranges from 0.5 to 1.5 hours, for ecgonine methyl ester from 3 to 4 hours, and for benzoylecgonine from 4 to 7 hours.[5-7] The principal urinary metabolites are benzoylecgonine and ecgonine methyl ester. Only small amounts of cocaine are excreted in urine. The elimination half-life for cocaethylene is 2.5 to 6 hours,[19,218,221] considerably longer than that for cocaine. This longer elimination half-life may contribute to cocaethylene's toxicity.

Analytical Methodology

The initial screening test for cocaine (benzoylecgonine) is typically immunoassay. For confirmation of a presumptive

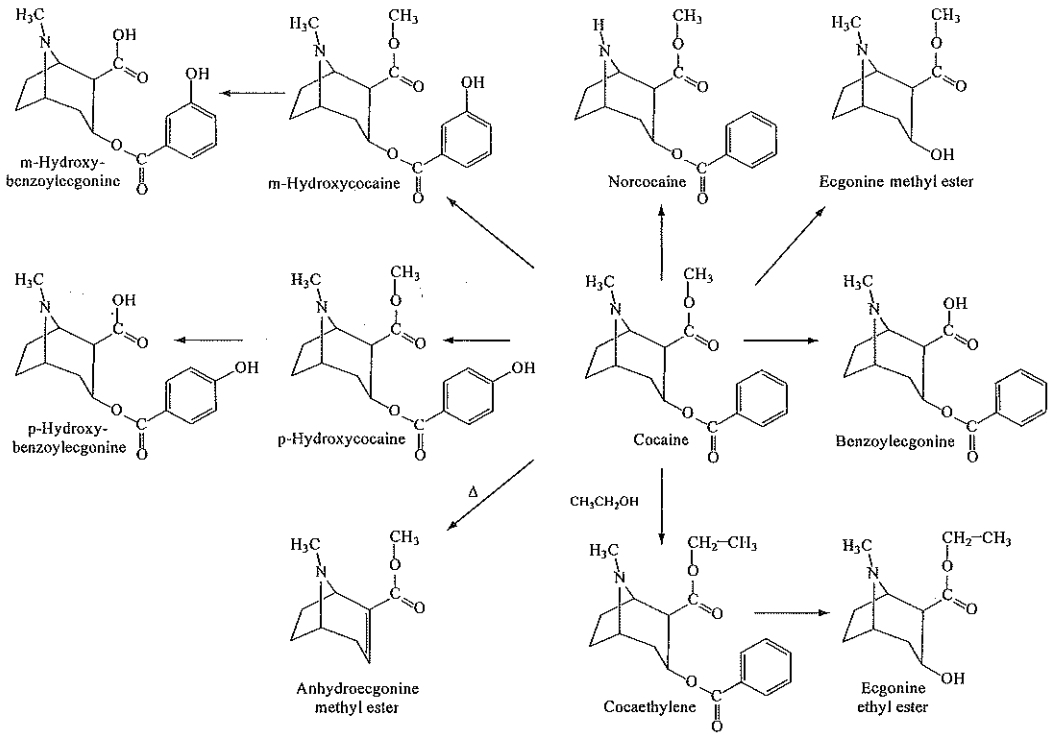

Figure 34-31 Metabolism and pyrolysis of cocaine.

positive, a quantitative drug measurement is performed using GC-MS.

Immunoassay. Screening immunoassays (e.g., Dade-Behring [EMIT], Abbott [FPIA]) are designed for the detection of benzoylecgonine. These assays have a 300-ng/mL cutoff and detect benzoylecgonine excretion for 1 to 3 days following cocaine use. However, for chronic heavy cocaine users, the detection time may extend to 10 to 22 days following the last dose,[474] apparently because of tissue storage of cocaine. Ordinarily cocaine may be detected in urine by chromatographic methods for only about 8 to 12 hours after use, but in heavy chronic users, this detection period may be 4 to 5 days.[104] These facts should be considered when interpreting the results of a urine drug test for individuals in drug treatment programs. A positive urine drug test for benzoylecgonine beyond 3 days after the last dose does not necessarily indicate continued use. For such purposes, it is better to monitor quantitatively the urinary excretion of benzoylecgonine, normalized to creatinine, over time.[47,440] Drug abstinence would be indicated by decreasing urinary excretion of cocaine metabolites. However, creatinine normalization may not always reliably indicate reuse.[374]

In meconium, *m*- and *p*-hydroxybenzoylecgonine (normally minor metabolites in adult urine) significantly contribute to the benzoylecgonine immunoreactivity.[346,427]

The consumption of Peruvian coca tea, which is not legally imported into the United States, may result in a positive urine test for benzoylecgonine.[187]

Gas Chromatography-Mass Spectrometry. A positive screening result for benzoylecgonine obtained by immunoassay is confirmed by GC-MS analysis of the urine specimen. A GC-MS method for benzoylecgonine is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). This method uses normalized ion ratios as this compensates for any changes in the mass spectrometer ion source at the time of analysis[55] and either a single or multiple calibrators.[151,394]

Gamma-Hydroxybutyrate (GHB)

Gamma-hydroxybutyrate (γ-hydroxybutyrate/GHB) is a naturally occurring metabolite of γ-aminobutyric acid (GABA) and like GABA, it may possess CNS neuroinhibitory activity via specific GHB receptors.

Pharmacological Response

GHB was investigated as an anesthetic agent but was discontinued because of its lack of analgesia and because of adverse side effects including seizures. It is used outside the United States to treat alcohol and opioid withdrawal and was recently approved in the United States under the name Xyrem for the treatment of narcolepsy.

When ingested, GHB stimulates dopamine release, leading to pleasurable effects such as euphoria, muscle relaxation, and heightened sexual desire.[48,113] It also has CNS depressant effects resulting in sedation and hypnosis. Because GHB was reported to enhance growth hormone release, it has been used as a steroid alternative by body builders and athletes. Athletes also have used GHB as a sleep aid because they believe it promotes rapid recovery from vigorous repetitive competition. These properties and the availability of GHB in dietary supplements led to growing recreational abuse of the

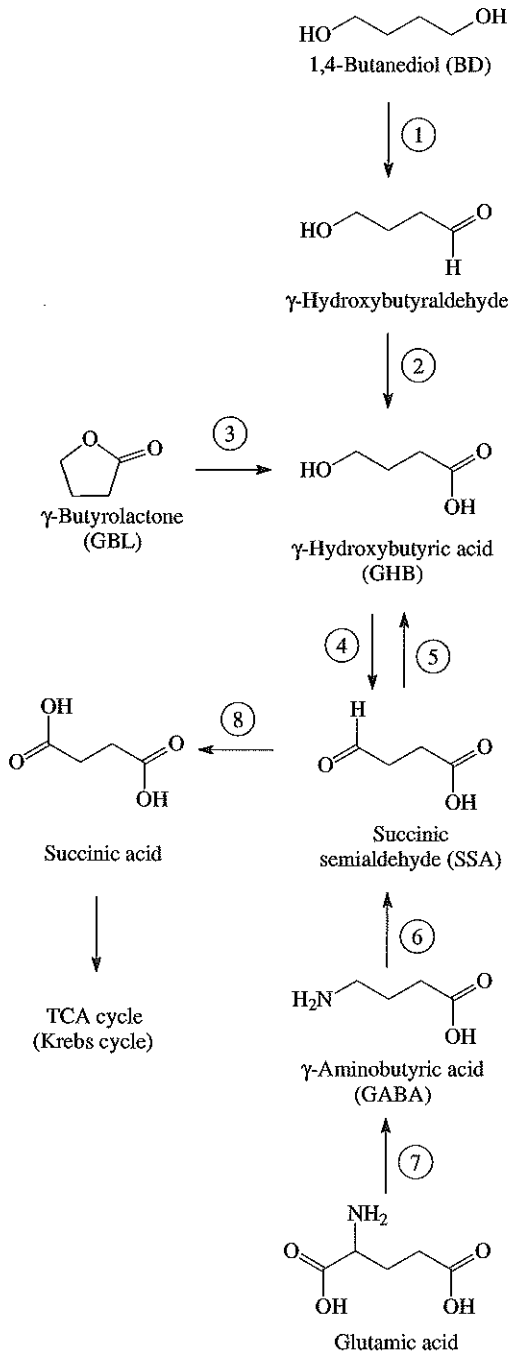
drug. GHB has become popular as a euphorigenic club drug, most often used in combination with alcohol and also with MDMA or cocaine to "mellow" their adverse stimulant properties. Its rapid onset and hypnotic and short-term amnestic properties have resulted in the use of GHB for drug-facilitated sexual assault (date rape drug).

The FDA removed GHB from consumer products in 1990 in response to its increasing abuse and danger. This action led to its replacement by γ-butyrolactone (GBL), a GHB precursor (Figure 34-32) that is also used as a chemical cleaning agent and solvent. GBL is more rapidly absorbed and has greater bioavailability compared with GHB.[420] GBL is also readily converted ex vivo to GHB by its treatment with an alkaline solution. Health supplement products containing GBL (e.g., RenewTrient, Revivarant, Reinforce) have also now been removed from the market only to be replaced by another GHB precursor, 1,4-butanediol (Figure 34-32),[500] also present in household cleaning agents and industrial solvents. GHB itself has a number of colorful street names including liquid ecstasy, easy lay, zonked, and Georgia home boy. Diet supplements that contain 1,4-butanediol include SomatoPro and Revitalize Plus.

Toxic manifestations of GHB or its precursors include nausea and vomiting, bradycardia, hypotension, coma, seizures, and severe but not prolonged respiratory depression.[113,274,309] Periods of agitation may be interspersed between apnea and unresponsiveness. It is uncertain whether this agitation is a direct GHB effect or a consequence of co-ingested stimulant drugs. Deaths have been reported but are almost always associated with co-ingestion of alcohol or other drugs.

GHB is rapidly absorbed from the GI tract and its onset of action is extremely rapid. Loss of consciousness may occur within 15 to 30 minutes. The duration of response is also short, typically 1 to 3 hours for normal dose and 2 to 4 hours with excessive dose. Overdose leading to coma and respiratory depression requiring assisted ventilation generally resolves in <6 hours. Frequent use of GHB in high dose may produce tolerance and dependence despite its short duration of action. A withdrawal syndrome consisting of tremor, agitation, paranoia, delirium, hallucinations, confusion, tachycardia, and hypertension may follow cessation from chronic heavy use.[130]

The CNS depressant effects of GHB may result from its interaction with endogenous GHB receptors and with $GABA_B$ receptors.[48] The latter are G-protein coupled receptors distinct from the $GABA_A$ receptors for depressant drugs, such as benzodiazepines and barbiturates. Of note, patients with GHB overdose do not respond to the opioid antagonist naloxone or to the benzodiazepine antagonist flumazenil. Fomepizole, an inhibitor of alcohol dehydrogenase, is likely beneficial for patients who ingest 1,4-butanediol.[420]



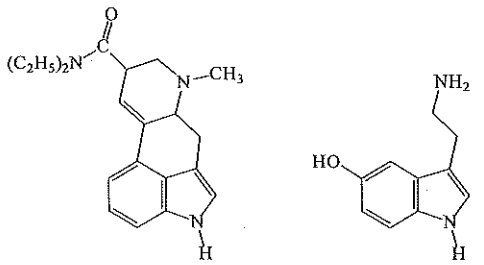


Figure 34-32 Metabolism of γ-hydroxybutyrate and its precursors. *1*, alcohol dehydrogenase; *2*, aldehyde dehydrogenase; *3*, lactonase; *4*, GHB dehydrogenase; *5*, SSA reductase; *6*, GABA transaminase; *7*, glutamate decarboxylase; *8*, SSA dehydrogenase.

Analytical Methodology

Immunoassays for GHB are not currently available. Thus chromatographic techniques (usually GC-MS) are required for analysis. GHB is rapidly eliminated ($t_{1/2}$ ~ 30 minutes) and therefore the detection period is <6 to 8 hours in plasma and <10 to 12 hours in urine. In drug-facilitated sexual assault cases, low GHB concentrations may be observed in urine (1.0 to 610 mg/dL).[302] Because GHB is produced endogenously, it is important to establish an appropriate analytical cutoff above which only exogenous GHB is mea-

LSD Serotonin

Figure 34-33 Chemical structure of LSD and serotonin.

sured. In urine, endogenous levels are well below 1.0 mg/dL and this is the recommended analytical cutoff.[265,495]

A GC-MS method for measuring GBH is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). In this method, a urine specimen is treated with acidified acetonitrile and then dehydrated by evaporation. GHB is converted to its bis-trimethylsilyl derivative and analyzed using GHB-D_6 as internal standard.

Lysergic Acid Diethylamide (LSD)

LSD shares structural features with serotonin (5-hydroxytryptamine; Figure 34-33), a major CNS neurotransmitter and neuromodulator.[456,487] LSD is synthesized from D-lysergic acid, a naturally occurring ergot alkaloid found in the fungus *Claviceps purpurea,* which grows on wheat and other grains. During synthesis, some LSD epimerizes to iso-LSD, which is inactive (Figure 34-33).

Pharmacological Response

LSD is an extremely potent psychedelic indolealkylamine.[32] The drug LSD binds to serotonin receptors in the CNS and acts as a serotonin agonist. The principal psychological effects of LSD are perceptual distortions of colors, sound, distance, and shape; depersonalization and loss of body image; and rapidly changing emotions from ecstasy to depression or paranoia. These hallucinogenic actions of LSD are stereoselective, elicited only by the D-isomer.[487] There has been a resurgence in the use of LSD, previously popular as a drug of abuse during the 1960s. The Department of Defense includes LSD among the drugs for which urine testing is required (see Table 34-8).

The physiological effects of LSD are related to its sympathomimetic actions and include mydriasis (most frequent and consistent), tachycardia, increased body temperature, diaphoresis, and hypertension; at higher doses, parasympathomimetic actions may be observed (e.g., salivation, lacrimation, nausea, and vomiting [muscarinic actions]). Neuromuscular effects may include paresthesia, muscle twitches, and incoordination (nicotinic actions).[456,487]

The most common adverse effects of LSD are panic attacks. In addition, unpredictable recurrence of hallucinations (flashbacks) may occur weeks or months after last drug use and LSD may elicit psychotic reactions (thought disorders, hallucinations, depression, and depersonalization). LSD is used illicitly because of its hallucinogenic effects. There is no evidence that repeated LSD use results in dependence or withdrawal symptoms.[456,487]

Popular dosage forms include powder, gelatin capsule, tablet, or LSD-impregnated sugar cubes, filter paper, or postage stamps. The drug is rapidly absorbed from the GI tract; the effects begin within 40 to 60 minutes, peak at about 2 to 4 hours, and subside by 6 to 8 hours. The elimination $t_{1/2}$ is about 3 hours. The metabolism of LSD in humans is incompletely understood, but 2-oxo-3-hydroxy-LSD is present in urine at concentrations 10- to 43-fold greater than LSD (Figure 34-34).[363,364,380] *N*-demethyl-LSD is also present in urine specimens, but at concentrations approximately equivalent to those of LSD. The other metabolites described in Figure 34-34 are among those identified in animals, but as yet not conclusively identified in man. Iso-LSD is not a metabolite but is formed by nonenzymatic epimerization of LSD during synthesis or during storage of urine at alkaline pH and elevated temperature.[391]

The clinical effects of LSD ingestion are usually benign and require no medical intervention. However, panic attacks may be severe and require treatment with diazepam; LSD-induced psychosis may be treated with haloperidol. Rare cases of massive overdose have resulted in life-threatening hyperthermia, rhabdomyolysis, acute renal failure, hepatic failure, DIC, respiratory arrest, and coma. Few if any well-documented deaths directly related to LSD ingestion have been reported.

Analytical Considerations

Because of the very high potency of LSD and therefore low typical dose (~50 µg) and its rapid and extensive metabolism (Figure 34-34), only about 1% to 2% of the drug is excreted unchanged in urine.[380] Thus detection of LSD presents an especially difficult analytical challenge. Even with sensitive assays, the detection window for LSD is generally only 12 to 24 hours.[380]

Immunoassays targeted to detect LSD at the usual cutoff concentration of 500 pg/mL include DPC RIA, Roche Abuscreen RIA, CEDIA, EMIT, KIMS, and ELISA. Confirmation is typically performed by GC-MS[162,355] at the U.S. Department of Defense established cutoff concentration of 200 pg/mL. Not unexpectedly, immunoassays are less specific for LSD compared with GC-MS. Although the metabolites 2-oxo-3-hydroxy-LSD and *N*-demethyl LSD generally cross react only when present at about 100 to 200 times that for LSD,[477] other as yet identified metabolites may potentially account for some instances of nonconfirmed positive immunoassay response.[97,489] However, true false-positive results due to various therapeutic drugs occur, especially with the EMIT assay.[97,381,477] The detection window may be extended, perhaps twofold to threefold, by including 2-oxo-3-hydroxy-LSD in the confirmatory test using sensitive techniques such as GC-MS-MS,[380] LC-MS-MS,[248,364] or

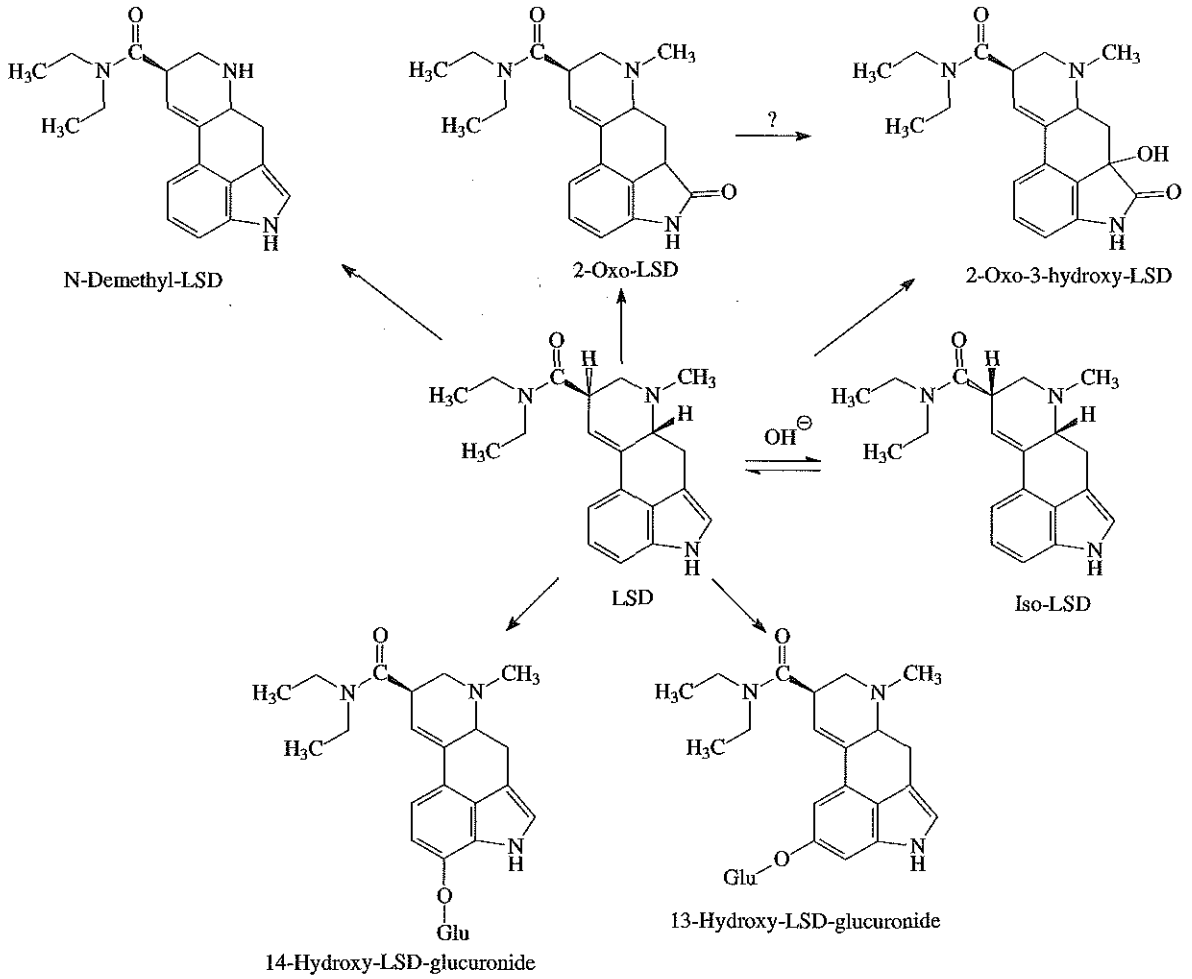

Figure 34-34 Metabolism of LSD.

LC-MS.[363] Likewise, detection of iso-LSD in addition to LSD may also extend the detection interval.[93] Urine specimens should be protected from sunlight, bright fluorescent light, or elevated temperature at alkaline pH in order to avoid degradation of LSD[275] and 2-oxo-3-hydroxy-LSD or epimerization of LSD to iso-LSD.[275,391]

Opioids/Opiates

Opioid is a general term applied to all substances with morphine-like properties. The term opiate is used to describe naturally occurring or semisynthetic analgesic alkaloids derived from opium, the dried milky juice from the unripe seeds of the poppy plant. Morphine is the principal and prototypical analgesic alkaloid of opium. Opium also contains smaller amounts of codeine. Some important semisynthetic derivatives of morphine include heroin, oxycodone, hydrocodone, oxymorphone, hydromorphone, and levorphanol. Codeine may also be synthesized by 3-methylation of morphine. Synthetic agents with morphine-like properties include propoxyphene, methadone, meperidine, and fentanyl (Figure 34-35).[184]

Pharmacological Response

Opiates are used clinically because of their analgesic properties. Opiates also cause sedation, euphoria, respiratory depression, orthostatic hypotension, diminished intestinal motility, nausea, and vomiting. The major manifestations of morphine overdose are coma, miosis (pinpoint pupils), and respiratory depression. Pulmonary edema often is a complication of morphine overdose, and death may result from cardiopulmonary arrest. Treatment for morphine overdose includes administration of the opiate antagonist naloxone (Narcan), which dramatically reverses the effects of morphine.[184]

Endogenous opioid receptors have been identified, cloned, and sequenced. They are members of the trimeric G-protein-binding superfamily, which are coupled to signal transduction via adenyl cyclase, and to Ca^{2+} and K^+ ion-channel transport.[184] Three major receptor subtypes are known (mu, kappa, and delta). Mu (μ) receptor activation results in sedation, euphoria (via dopamine release), analgesia, respiratory depression, and GI dysmoility. Kappa (κ) receptors mediate spinal analgesia, miosis (via acetylcholine

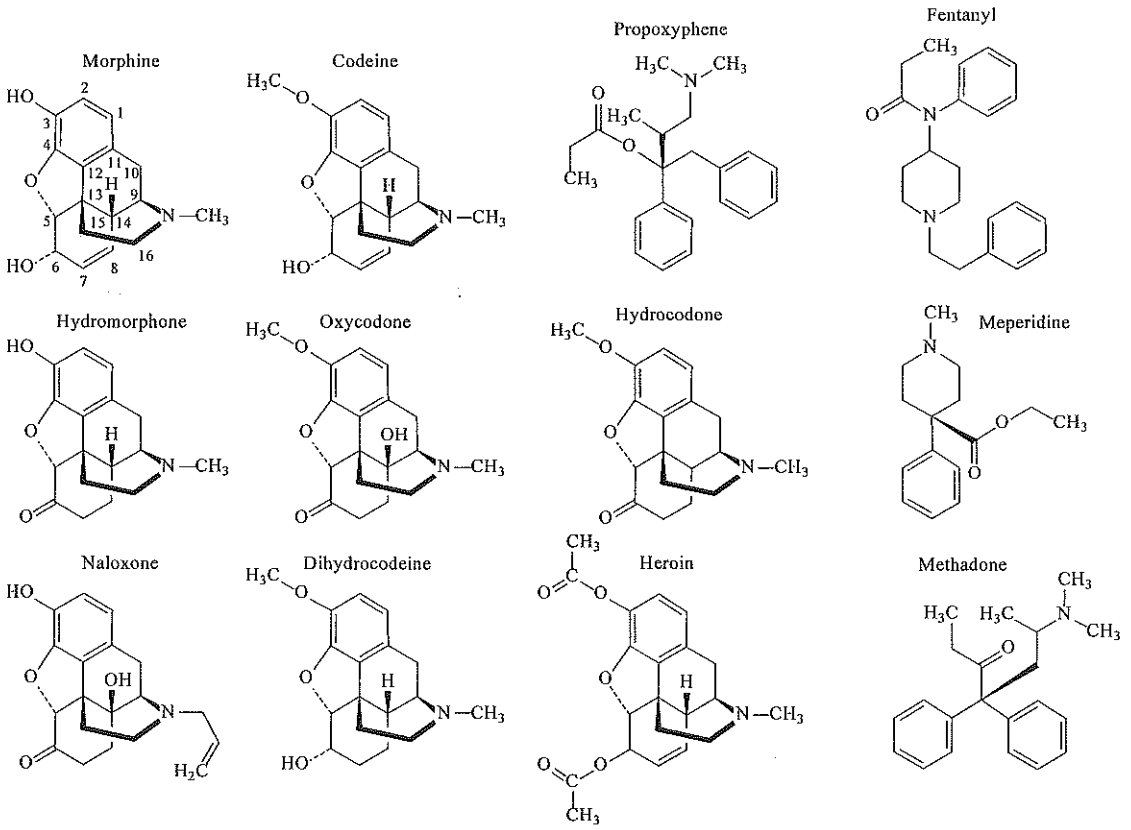

Figure 34-35 Chemical structures of representative opioids and of the opioid antagonist naloxone.

release), diuresis (inhibition of ADH release), and a dysphoric response. Delta (δ) receptors are responsible for brain and spinal analgesia. Some opioids (e.g., codeine and hydrocodone) are effective antitussive agents, but the central receptors responsible for this action have not been clearly identified. Most opioid agonist are rather nonselective in binding to the receptor subtypes. Naloxone (Narcan) and naltrexone (Trexan) are opioid receptor antagonists. Endogenous ligands for these receptors are peptides referred to as endorphins. They are believed to mollify pain and produce euphoria. The "runner's high" subsequent to intense physical activity is considered to be endorphin mediated.

Because of their analgesic and euphorigenic properties, opiates have a high abuse potential. Chronic use of morphine leads to tolerance and to both physical and psychological dependence. Withdrawal from morphine addiction may be treated by the administration of methadone, a long-lasting, orally active opiate. Over time, the goal is to replace opiate use with methadone, and then gradually wean addicts from the methadone. Other therapeutic agents for treating morphine addiction include naltrexone, a long-acting opiate antagonist; levo-α-acetylmethadol (LAAM), a long-acting (~4 days) agonist; and clonidine, a central α_2-adrenergic agonist antihypertensive agent with CNS actions similar to opiates.[327] Buprenorphine, a partial μ receptor agonist and weak κ receptor antagonist, has recently been approved for treatment of opioid addiction.[424a]

Heroin (diacetylmorphine) is the form of morphine most favored by opiate abusers because of its rapid onset of action. It is generally administered by IV or subcutaneous injection or, less frequently, by smoking or nasal insufflation.[417] Heroin itself is not active, but it is rapidly converted ($t_{1/2}$ < 6 min) to 6-acetylmorphine, which in turn is hydrolyzed ($t_{1/2}$ < 40 min) to morphine (Figure 34-36).[30,215] Both 6-acetylmorphine and morphine are pharmacologically active. Morphine (average elimination $t_{1/2} \approx 2$ hours; range, 1 to 8 hours) is inactivated mainly by glucuronide conjugation at the 3-hydroxyl (phenolic)group.[173] The average elimination half-life for morphine-3-glucuronide is 3 to 4 hours following IV,[173] 8 hours following intramuscular,[310] and 9 to 10 hours after oral morphine administration.[173] In addition to morphine-3-glucuronide, smaller amounts of morphine-6-glucuronide are also formed. However, unlike morphine-3-glucuronide, which is inactive, morphine-6-glucuronide has even more potent analgesic activity than morphine.[338,339] Moreover, the elimination $t_{1/2}$ for both glucuronides is similar but longer than for morphine[173]; therefore morphine-6-glucuronide accumulates in serum to greater concentrations than morphine. Thus morphine-6-glucuronide contributes to the analgesic and toxic effects of morphine, especially for patients with renal failure. Of the total morphine in urine, about 90% is morphine-3-glucuronide (50% to 75% of the morphine dose), and about 10% is free morphine.[35,372]

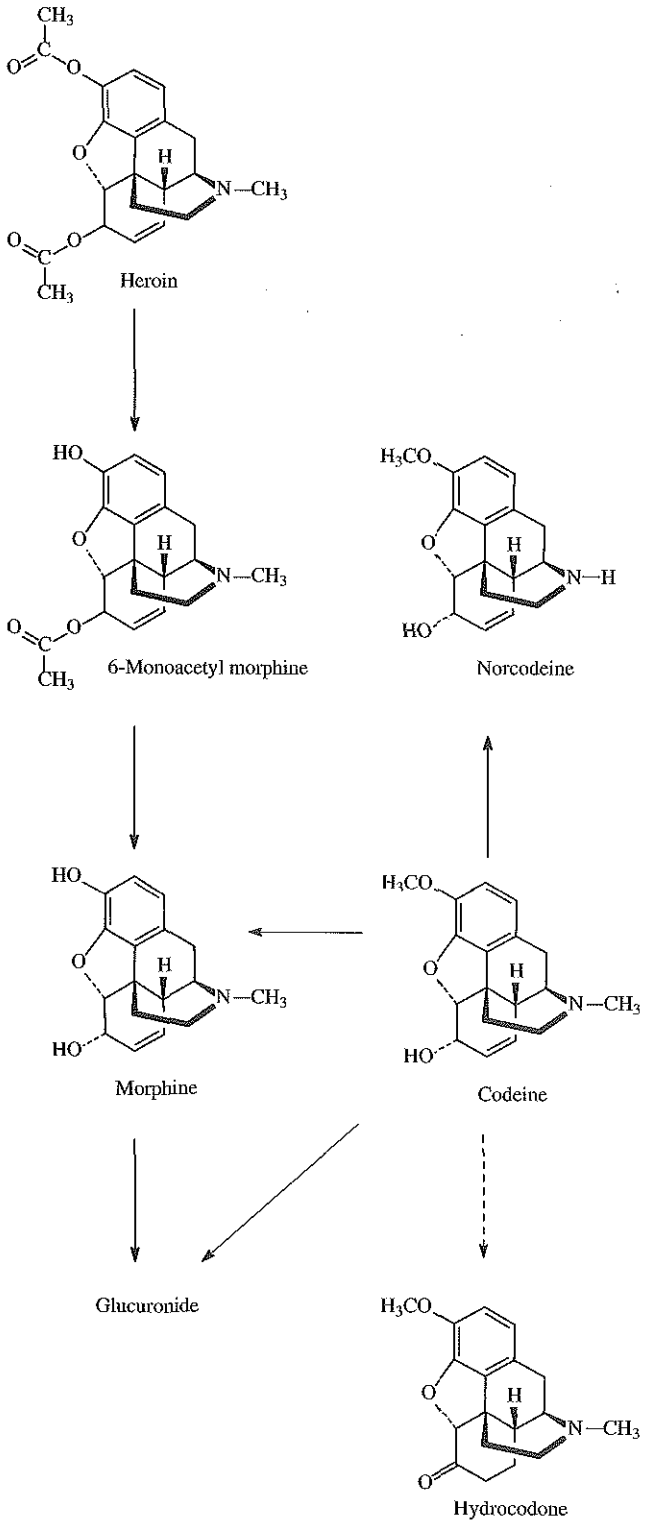

Figure 34-36 Metabolism of heroin and codeine.

Codeine has only about one tenth the analgesic potency of morphine; this is a consequence of the blocked phenolic hydroxyl group, which prohibits binding to opioid μ-receptors. A small amount of codeine (10%) is converted to morphine (see Figure 34-36), which accounts for the analgesic properties of codeine.[184] This O-demethylation is mediated by the cytochrome P_{450} isoform, CYP 2D6, which exhibits genetic polymorphism. Slow metabolizers produce very small amounts of morphine and thus experience no analgesia, whereas fast metabolizers experience a greater than expected analgesic effect.[497] A similar amount of norcodeine is formed by *N*-demethylation.[28] Hydrocodone is a minor metabolite.[344] Thus both codeine and morphine may be detected in urine following codeine ingestion. In addition, hydrocodone may also be detected in low concentration (~100 ng/mL) when urine codeine concentration is high (>5000 ng/mL).[344] Codeine is frequently combined with nonopiate analgesic agents (e.g., aspirin and acetaminophen); it is also an effective antitussive agent in some cough medicines.

Acetylcodeine is a common contaminant of heroin; thus both codeine and morphine may frequently be detected in urine following heroin use. Since morphine is a codeine metabolite, legitimate codeine use has been purported as explanation for a urine drug test positive for morphine and codeine when in fact heroin was used. In the case of heroin, the concentration of morphine exceeds that of codeine, whereas the reverse is true within the first 24 hours following codeine use. However, a reversal in the codeine:morphine ratio may occur in the late elimination period (>24 hours) subsequent to codeine administration.[106,372] This is a consequence of the longer terminal elimination phase for morphine compared with that for codeine. Dutt and coworkers have proposed a ratio of codeine:morphine >0.5 to be indicative of codeine use when the urine morphine concentration is >200 ng/mL; for morphine concentrations <200 ng/mL, any level of codeine would suggest its use.[128] These guidelines may not always be reliable in the late elimination phase.[83] With this cutoff, some subjects may test positive for morphine (>300 ng/mL) but negative for codeine (<300 ng/mL), even though codeine had been ingested.[106] Thus it is not always possible to distinguish between legitimate codeine use (e.g., from a cough preparation) and heroin or morphine abuse based on the codeine:morphine ratio in urine. A high degree of certainty for the ingestion of codeine only is provided by urine codeine >5000 ng/mL, with a codeine to morphine ratio <0.5.[83,263] Likewise the detection of the 6-acetylmorphine metabolite of heroin or of the 6-acetylcodeine heroin contaminant provides evidence for heroin use. However, the detection period for these acetyl derivatives is relatively short (~8 to 12 hours).[105,426] Contrary to measurements in urine, the plasma concentrations of morphine and codeine may more clearly distinguish between heroin and codeine use. Following a single dose of codeine, the plasma codeine concentration exceeded that for morphine (codeine:morphine >1.0) during the entire 23 hours postdose detection period.[254] With heroin use, the expected ratio is <1.0.[80]

The consumption of foods that contain poppy seeds (e.g., cakes, muffins, rolls, and bagels) may result in significant urinary excretion of morphine and codeine.[194,430] Obviously,

this may cause false incrimination of illicit opiate use as determined by drug testing programs. ElSohly and coworkers[143] proposed guidelines to eliminate poppy seed ingestion as the source of a positive urine opiate test. According to these guidelines, any of the following findings would eliminate poppy seed ingestion as the principal opiate source: morphine level >5000 ng/mL; codeine level >300 ng/mL; morphine:codeine ratio less than 2; morphine level >1000 ng/mL with no codeine. However, these guidelines may not always be reliable, because the consumption of poppy seed streusel was reported to result in urine samples with concentrations of morphine >5000 ng/mL and of codeine >300 ng/mL.[402] The morphine:codeine ratio, however, was always greater than 2. A lower morphine:codeine ratio would indicate codeine use and thus eliminate poppy seed ingestion as the opiate source. Detection of the heroin metabolite 6-acetylmorphine (see Figure 34-36) would also eliminate poppy seed ingestion.[105,322] However, 6-acetylmorphine is rapidly eliminated, so its detection in urine is limited to earlier than 24 hours (perhaps <8 hours) after heroin use.[105] Therefore the absence of 6-acetylmorphine does not rule out heroin or, of course, morphine use. To avoid some of the issues concerning poppy seed ingestion and the legitimate use of opiate medications, the Department of Defense established confirmatory cutoff concentrations of 4000 ng/mL morphine and 2000 ng/mL codeine, and also requires testing for 6-monoacetylmorphine (see Table 34-8). The Department of Health and Human Services likewise increased the screening and confirmatory cutoff concentrations from 300 ng/mL to 2000 ng/mL for morphine and codeine and also requires testing for 6-acetylmorphine (cutoff, 10 ng/mL).[84] Nevertheless, in the absence of 6-acetylmorphine, even these morphine cutoffs may not always eliminate poppy seed consumption. A 2003 study reported that the consumption of poppy seeds with unusually high morphine content resulted in a peak urine morphine concentration of 10,000 ng/mL.[441] For clinical purposes, the 300 ng/mL (or lower) cutoff is appropriate. From the foregoing discussion, it is obvious that caution is required when interpreting the results of a positive urine test for morphine and codeine.

Hydromorphone and oxymorphone are semisynthetic opiates that have about 8 to 10 times the potency of morphine. Hydromorphone has greater oral bioavailability than morphine; oxymorphone has limited IV use for postsurgical analgesia. Hydrocodone, oxycodone, and dihydrocodeine are 3 to 10 times more potent than codeine, and, like codeine, they have relatively good oral bioavailability. Hydrocodone is metabolized to hydromorphone and dihydrocodeine (Figure 34-37). This conversion is mediated by CYP 2D6, which exhibits genetic polymorphism. Rapid metabolizers form a greater amount of the more potent hydromorphone compared with slow metabolizers. The metabolite transformations for dihydrocodeine and oxycodone are presented in Figures 34-38 and 34-39, respectively. The elimination $t_{1/2}$ for all of these opiates is slightly longer than that for morphine, ranging from about 2.5 to 5 hours.[28,184]

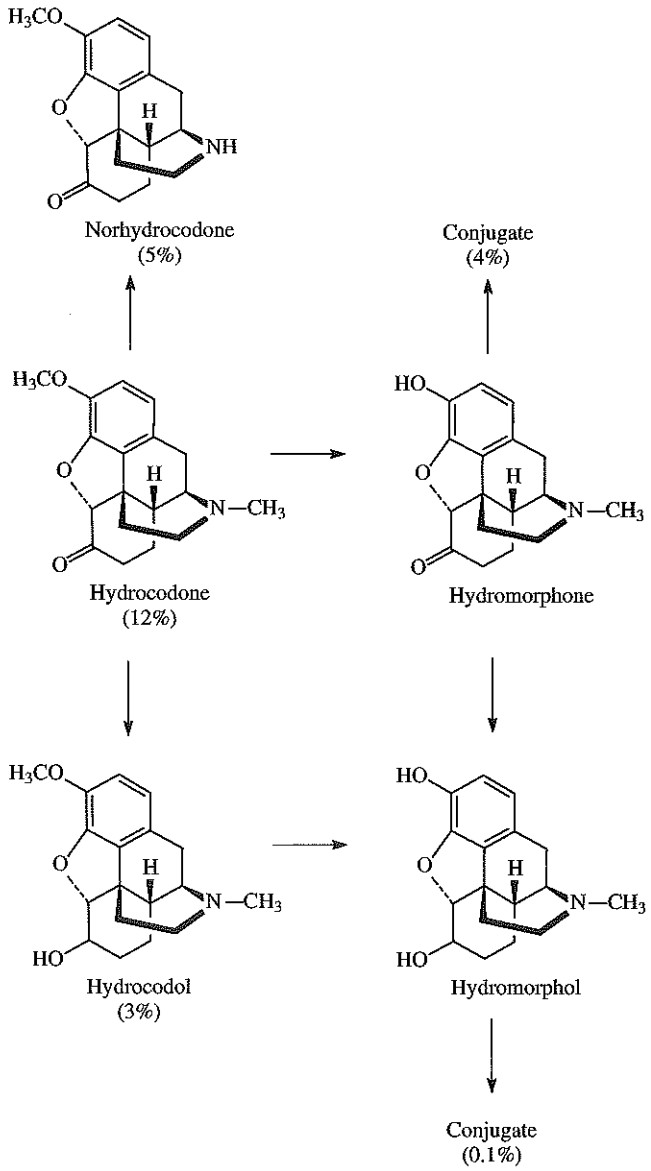

Figure 34-37 Hydrocodone and hydromorphone metabolic transformations. The figures in parenthesis are percent of a dose of hydrocodone excreted in urine. Rapid metabolizers excrete more hydromorphone conjugates (5.9%) compared with slow metabolizers (1.0%). Hydrocodol and hydromorphol exist as 6-α and β-stereiosomers. 6-α-hydrocodol is dihydrocodeine; 6-α-hydromorphol is dihydromorphine. For hydromorphone administration, 6% of the dose is excreted as the free parent drug and 30% as conjugates. Only trace amounts of hydromorphol conjugates are formed.

As for codeine, oxycodone is frequently formulated in combination with aspirin (Percodan) or acetaminophen (Percocet and Tylox). Therefore the detection of either salicylate or acetaminophen along with codeine or oxycodone in the urine of patients who display an opiate toxidrome should lead to the measurement of salicylate or acetaminophen in serum to assess their toxicity (see Salicylate and Acetaminophen sections). Alternatively, empiric quantitive serum acetaminophen and salicylate determinations are

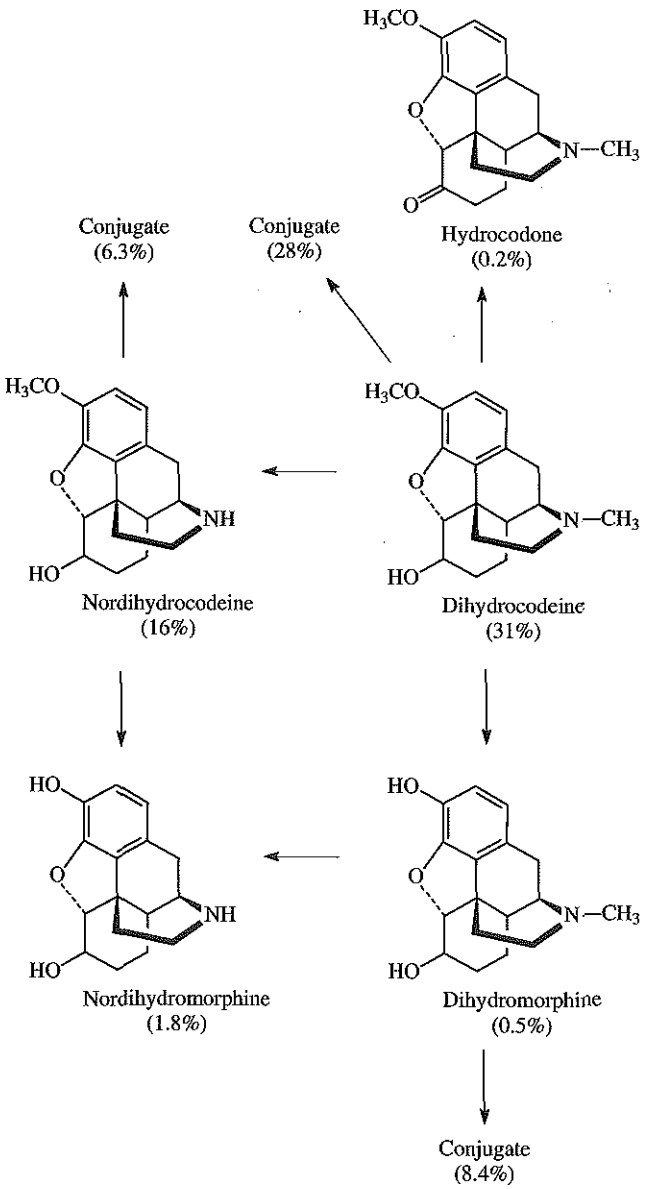

Figure 34-38 Metabolism of dihydrocodeine. Values in parentheses are percent of dose excreted in urine.

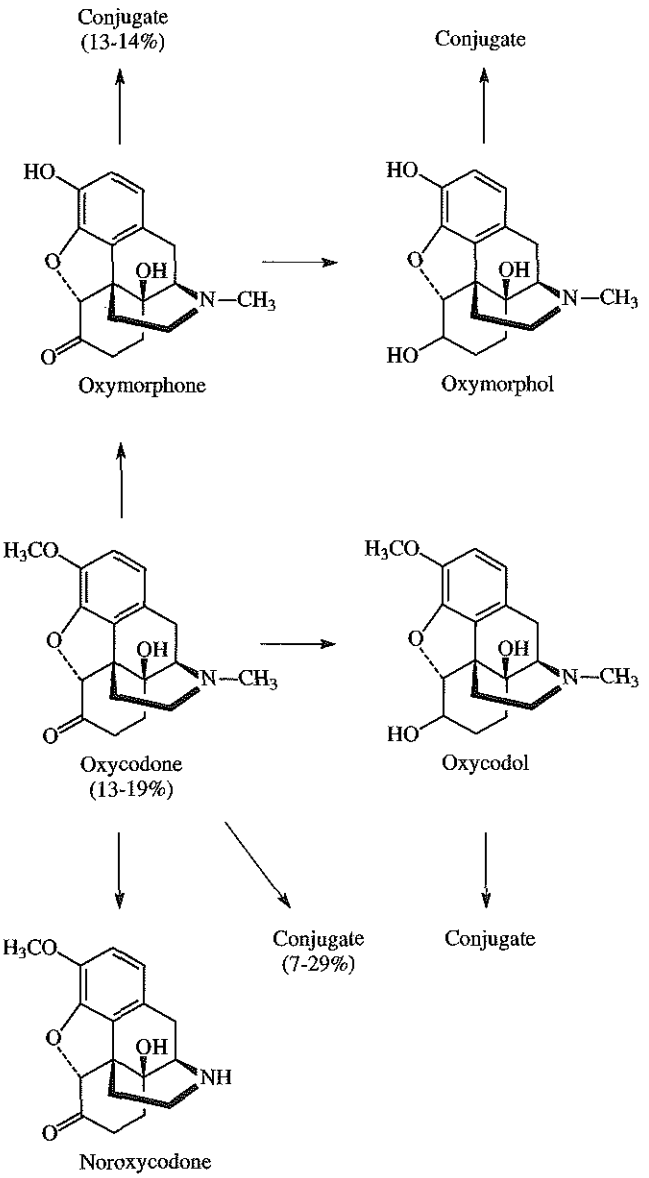

Figure 34-39 Metabolism of oxycodone and oxymorphone. Values in parentheses are percent of oxycodone dose excreted in urine. For oxymorphone dose, 1.9% is excreted as the parent drug, 44% as conjugates, and 3% as oxymorphol.

appropriate for patients with the opioid toxidrome. Non-combination oxycodone is also available in immediate and extended release dosage form. The later (OxyContin) is a very effective oral analgesic for patients with chronic pain (e.g., cancer patients). Illicit diversion of OxyContin has led to especially severe drug abuse, addiction, and several deaths in certain regions of the United States. The pills may be chewed or crushed to release for immediate availability the entire dose, which is intended for extended release over a 12-hour period. In some cases, the crushed pill may be snorted or solubilized for IV injection.

In pain management programs, urine drug testing is often employed to monitor compliance, diversion, or substitution for the prescribed drugs. Based on the results of such tests, an individual may be dismissed from the program. It is important for drug-testing laboratories to communicate relevant aspects of the metabolic interconversion of opiates to physicians responsible for these programs. Otherwise the detection of hydromorphone and dihydrocodeine in addition to prescribed hydrocodone (Figure 34-37) may be falsely interpreted as substitution. Likewise a urine specimen that contains prescribed codeine plus its morphine metabolite or very low concentrations (~100 ng/mL) of the minor hydrocodone metabolite (detected when codeine is >5000 ng/mL) should not be interpreted as heroin and/or morphine or hydrocodone use. Alternatively a urine specimen that tests negative for prescribed codeine but positive for hydromorphone or hydrocodone would clearly indicate substitution.

Monitoring compliance for oxycodone in pain management programs is problematic because of the low cross-

reactivity of oxycodone in most opiate immunoassays (e.g., >5000 ng/mL oxycodone for positive result with EMIT assay using a 300 ng/mL morphine cutoff). In this instance, a false-negative opiate immunoassay test may lead to an accusation of oxycodone diversion. The direct determination of oxycodone by GC-MS is more appropriate to monitor compliance for this drug. Alternatively a new, single use, lateral-flow immunoassay test device (see also section on On-Site Drug Test) is available for the initial detection of oxycodone at 100 ng/mL cutoff (Rapid One OXY; American Bio Medica Corp, New York).

Analytical Methodology

The initial screening test for opiates is most often immunoassay. For confirmation of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.[383]

Immunoassay. Immunoassays are rapid, convenient procedures for screening urine specimens for opiates. For clinical application, a cutoff of 300 ng/mL morphine (or morphine equivalents) is commonly used to distinguish negative from positive urine specimens whereas a cutoff of 2000 ng/mL is mandated by SAMHSA for workplace drug screening. The commercial immunoassays for opiates are designed primarily for the detection of morphine and codeine. The degree of cross-reactivity with morphine-3-glucuronide and with other opiates varies among the immunoassays. In general, cross-reactivity with oxycodone and oxymorphone is very low.[281,416] False-positive responses for some immunoassays have resulted from dextromethorphan, diphenhydramine, ephedrine/pseudoephedrine, doxylamine, chlorpheniramine, brompheniramine,[418] quinolone antibiotics,[17,304] and rifampin.[114,458]

The detection period following morphine or codeine use varies somewhat with the dose, the cutoff concentration for the immunoassay, and the degree of cross-reactivity with the glucuronide conjugates. In general, urine specimens test positive for 1 to 3 days following morphine (or heroin) or codeine use when assayed at a cutoff of 300 ng/mL. At a cutoff of 2000 ng/mL, the detection period following single-dose heroin decreased from 24 to 48 hours (300 ng/mL cutoff) to 12 to 24 hours but test specificity increased.[458] The applicability of the higher cutoff has been challenged by the finding of 6-monoacetylmorphine in a high percentage of specimens with morphine <2000 ng/mL in cases of heroin-associated death.[317]

Gas Chromatography-Mass Spectrometry. A positive screening result for opiates obtained by immunoassay is confirmed by GC-MS analysis of the urine specimen.[383] A GC-MS method is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Dextromethorphan

Dextromethorphan is structurally related to the opioids, but it does not bind to opioid receptors at normal dose and is thus devoid of analgesic activity.[327] The (–) isomer of dextromethorphan, levorphan (not available in the United States), is a potent opioid analgesic, and an example of the stereoselective nature of opioid receptor binding.

Dextromethorphan does have antitussive activity comparable with that of codeine. It is present in a number of cough medications, often in combination with antihistamines, nasal decongestants, aspirin, and acetaminophen. At very high dose, dextromethorphan may cause lethargy or somnolence, agitation, ataxia, nystagmus, diaphoresis, and hypertension.[332,484,498] The abuse of dextromethorphan, especially by adolescents and teenagers who refer to it as "DMX," has become widespread in some locations. Abusers describe feelings of euphoria; dissociative effects, such as a sense of floating; and hallucinations. Discontinuation of the drug is frequently followed by dysphoria and depression. Most preparations contain dextromethorphan as the bromide salt. Excessive ingestion of dextromethorphan may result in bromide poisoning and in a negative serum anion gap consequent to the disproportional response to bromide with common methods for chloride analysis.

Dextromethorphan is metabolized to dextrophan (Figure 34-40) by the cytochrome P_{450} isozyme 2D6 (CYP 2D6), which exhibits genetic polymorphism. Dextrophan also lacks analgesic activity, but it does retain antitussive action. Dextrophan may be responsible for the more pleasant psychotropic effects of high dose dextromethorphan, whereas the parent drug may cause dysphoria, sedation, and ataxia.[498] Thus poor metabolizers (deficient in CYP 2D6 activity) may be less prone and extensive metabolizers more prone to continue the abuse of dextromethorphan.

Dextrophan and to a lesser degree dextromethorphan bind to the PCP and ketamine binding site on the *N*-methyl-D-aspartate (NMDA) receptor, which probably accounts for their similar dissociative psychotropic actions[327] (see Phencyclidine and Ketamine).

Dextrophan is the enantiomer of levorphanol, a potent opioid agonist available in the United States (Levo-Dromoran). Unless chiral analytical techniques are used, these enantiomers cannot be resolved. Drug testing laboratories that use conventional chromatographic techniques should not report a finding of levorphanol only, but should instead report dextrophan/levorphanol with a comment on their isomeric relationship and on the origin of dextrophan. This is especially important for pain management drug screening in which a false report of levorphanol may result in dismissal from the program. This report duality is advisable even when parent dextromethorphan is also detected. Savvy abusers of levorphanol conceivably may co-ingest dextromethorphan to conceal use of levorphanol. If such is suspected, chiral resolution of dextrophan and levorphanol would then be necessary.

Dextromethorphan cross-reacts with most immunoassays for opioids.[418]

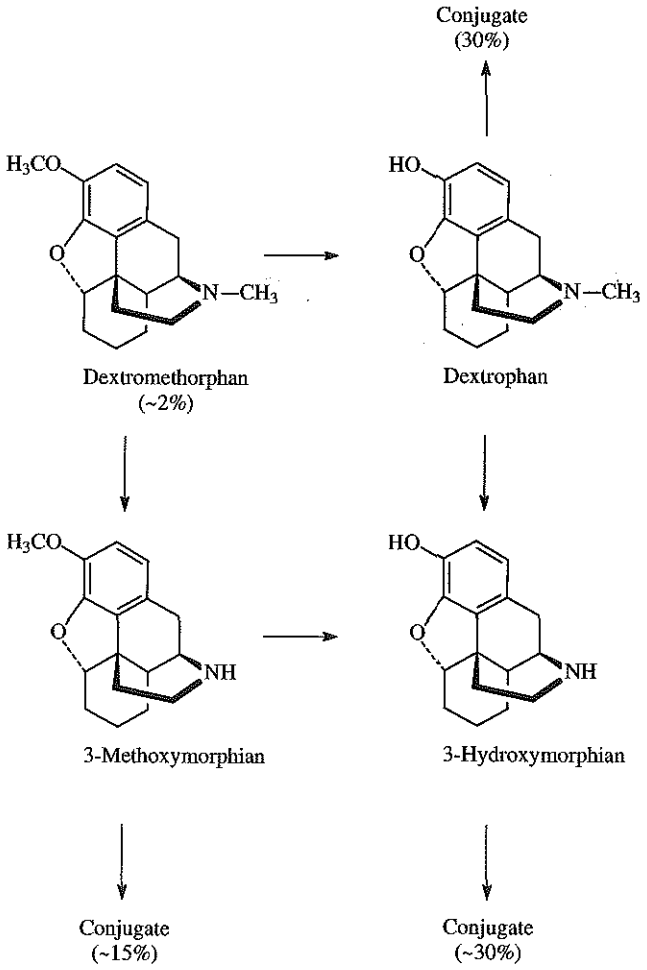

Figure 34-40 Metabolism of dextromethorphan. Values in parenthesis are percent of dose excreted in urine.

Methadone

Methadone is an opioid with similar structure to propoxyphene (see Figure 34-35).

Pharmacological Response

The major pharmacological actions of methadone, mediated by μ- and δ-receptor interactions, are similar to those of other opioids and include analgesia, sedation, respiratory depression, miosis, antitussive effects, and constipation. Methadone is administered as a racemic mixture (R,S-[±]-methadone), but the analgesic activity is due almost entirely to the R(−)-isomer. When administered intramuscularly, methadone and morphine have equivalent analgesic potency. In contrast to morphine, methadone retains about 50% of its intramuscular analgesic potency when taken orally.[184]

Methadone is rapidly absorbed from the GI tract with an onset of action within 30 to 60 minutes. The elimination $t_{1/2}$ is long (15 to 55 hours) compared with morphine ($t_{1/2}$ = 1 to 8 hours). Because of the longer elimination $t_{1/2}$, methadone accumulates in blood and tissue following repeated doses, and this presumably contributes to its relatively long duration of action (6 to 8 hours).[184,268]

Methadone is used clinically (1) for relief of pain, (2) to treat opioid abstinence syndrome, and (3) to treat heroin addicts in an attempt to wean them from illicit IV drug use.[439]

Tolerance to the effects of methadone develops with repeated doses, but more slowly than is true for morphine. Likewise, withdrawal develops more slowly and is generally less intense but more prolonged than morphine withdrawal. Withdrawal symptoms include weakness, anxiety, insomnia, abdominal discomfort, sweating, and hot and cold flashes.[184]

In overdose, methadone causes CNS and respiratory depression, miosis, bradycardia, hypotension, circulatory collapse, hypothermia, coma, seizures, and pulmonary edema (although less frequently than morphine). Treatment for methadone overdose includes supportive measures to maintain adequate respiration and blood pressure, and the administration of the opioid antagonist naloxone to reverse the effects of methadone.[268,485] If repeated administration of naloxone is required, patients should be monitored for 48 to 72 hours following overdose. Dialysis is not an effective treatment modality, because methadone has a large volume of distribution (V_d = 4 to 5 L/kg) and is highly protein bound (87%).[184]

Methadone is metabolized in the liver primarily to 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) and 2-ethyl-5-methyl-3,3-diphenylpyrroline (EMDP) (Figure 34-41). The principal urinary excretion products are methadone (5% to 50% of dose) and EDDP (3% to 25% of dose); relatively more methadone (pK_a 8.62) than EDDP is excreted when urine is acidic.[33] Monitoring compliance in methadone maintenance programs with urine drug testing may be confounded by the declining dose over time and the pH-dependent urinary excretion of methadone. For such purpose, measurement of EDDP was more effective than methadone in a large study.[170] Moreover, a methadone-positive, EDDP-negative specimen would indicate specimen spiking by a noncompliant patient.

Analytical Methodology

The initial screening test for methadone is typically immunoassay. For confirmation of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.

Immunoassay. Screening immunoassays for methadone include DPC (RIA), EMIT, CEDIA, TDx, and Roche Abuscreen. A typical assay cutoff concentration is 300 ng/mL. No cross-reactivity with EDDP or EDMP has been reported; however, (−)-α-acetylmethadol (LAAM),[89] a long-acting methadone analog, and verapamil metabolites[277] may cross-react in some assays. Methadone may generally be detected in urine for up to 72 hours following ingestion. Immunoassays specific for EDDP are available (CEDIA; DRI).

Gas Chromatography-Mass Spectrometry. A positive screening result for methadone obtained by immunoassay is

confirmed by GC-MS analysis of the urine specimen. A GC-MS method for methadone is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Propoxyphene

Propoxyphene is an opioid structurally similar to methadone (see Figure 34-35).

Pharmacological Response

Propoxyphene is a widely prescribed narcotic analgesic with a potency approximately one-half that of codeine when each is orally administered. Typical oral doses of propoxyphene have about the same analgesic effect as 600 mg aspirin.[184] Only the (+)-isomer (Darvon, others) binds to μ receptors to produce analgesia; the (−)-isomer (Novrad; appropriately the mirror image spelling of Darvon) is devoid of analgesic activity but is effective as an antitussive agent. Propoxyphene is prescribed most often as a combination with acetaminophen or aspirin.[184]

Propoxyphene is rapidly absorbed and undergoes extensive hepatic first-pass metabolism to norpropoxyphene (Figure 34-42). The elimination $t_{1/2}$ for propoxyphene is about 15 hours (8 to 24), and that for norpropoxyphene is 27 hours (24 to 34). Norpropoxyphene may contribute to the analgesic and cardiotoxic effects of propoxyphene.[36]

Propoxyphene overdose may result in nausea, vomiting, and drowsiness or in more severe cases, CNS depression, convulsion, respiratory depression, and cardiovascular collapse. Cardiac arrhythmia atypical for opioid overdose is a consequence of blockade of myocardial Na^+ channels, primarily by norpropoxyphene (similar to tricyclic antidepressant cardiotoxicity). Death, usually a result of respiratory depression and cardiac arrhythmia, is more common when propoxyphene is ingested with another CNS depressant, such as alcohol.[184,327]

Propoxyphene and norpropoxyphene may be quantified in serum by GC or HPLC, but because of the poor correlation between serum concentration and degree of impairment or prognosis, such quantitative information is generally not helpful in cases of propoxyphene overdose. However, their qualitative identification in urine may be useful to help confirm or establish the cause of a patient's symptomatology. Because propoxyphene is frequently taken in combination with acetaminophen or aspirin, quantitation

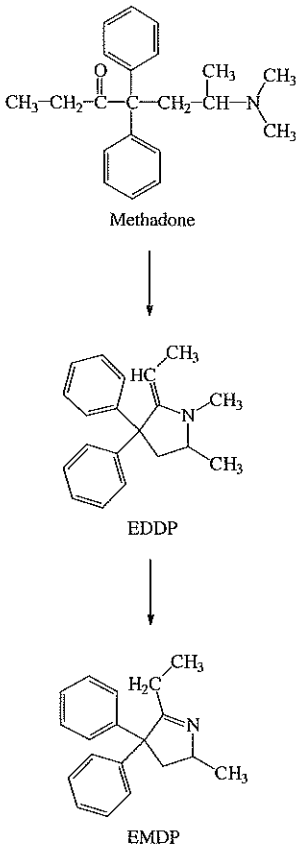

Figure 34-41 Metabolism of methadone.

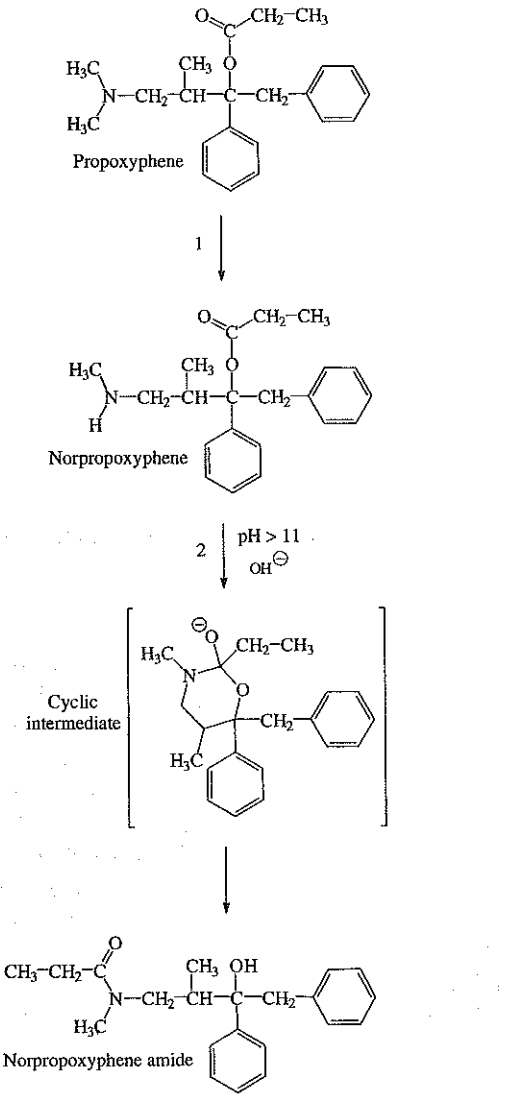

Figure 34-42 *1, N*-Demethylation of propoxyphene; 2, Base-catalyzed conversion of norpropoxyphene to norpropoxyphene amide.

of acetaminophen and salicylate in serum is advisable to assess their possible toxicity.

Naloxone is effective in reversing the CNS and respiratory depressant actions of propoxyphene but has little effect on the cardiotoxicity. The latter may be treated with $NaHCO_3$ to reverse the Na^+-channel inhibition (a similar therapeutic rationale applies to the treatment of tricyclic antidepressant cardiotoxicity). Because propoxyphene has a large volume of distribution (10 to 18 L/kg) and is highly protein bound (70% to 80%), hemodialysis is of little value in instances of serious overdose. Forced diuresis likewise is of little value because only about 1% is eliminated in urine as unchanged propoxyphene.

Analytical Methodology

The initial screening test for propoxyphene is typically immunoassay. For confirmation of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.

Immunoassay. Immunoassays for propoxyphene (EMIT, CEDIA, FPIA) are designed for the detection of the parent drug; cross-reactivity with norpropoxyphene, present in much greater concentration than the parent drug, is weak, especially for EMIT. In general, propoxyphene may be detected for about 2 days following use. Diphenhydramine may produce a false-positive response with EMIT.[395]

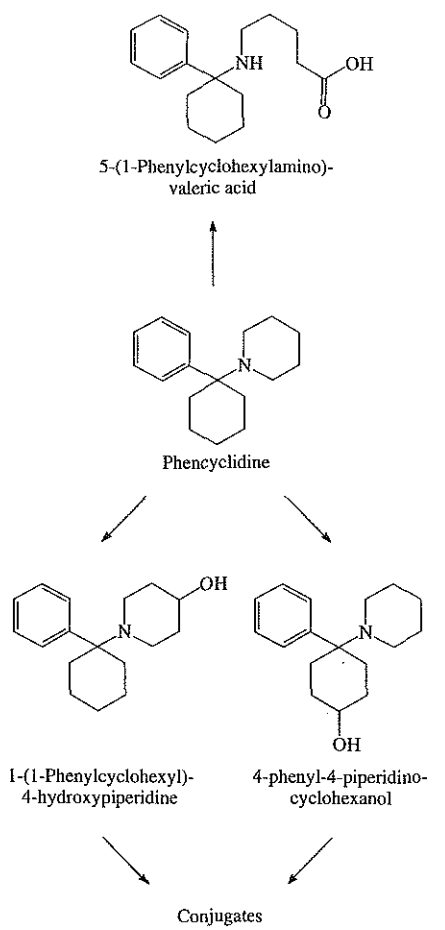

Figure 34-43 Metabolism of PCP.

Gas Chromatography-Mass Spectrometry. A positive screening result for propoxyphene obtained by immunoassay is confirmed by GC-MS analysis of the urine specimen for norpropoxyphene. Because norpropoxyphene is present in urine at considerably greater concentrations than propoxyphene, and because the latter has poor gas chromatographic characteristics, confirmation analysis by GC-MS is directed at the determination of norpropoxyphene after its conversion to norpropoxyphene amide. A GC-MS method for norpropoxyphene is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Phencyclidine and Ketamine

Phencyclidine (PCP) is a potent veterinary analgesic and anesthetic; it is sometimes used illicitly by humans in cases of drug abuse, leading to serious psychological disturbances. Ketamine is a rapid-acting general anesthetic and anesthesia adjunct, administered intramuscularly and intravenously.

Pharmacological Response

PCP and ketamine share common structural features (Figures 34-43 and 34-44) and possess similar pharmacological actions. They are classified as dissociative anesthetics because they cause functional dissociation of pain perception, consciousness, movement, and memory.[335] Thus an anesthetic dose produces profound analgesia, but the indi-

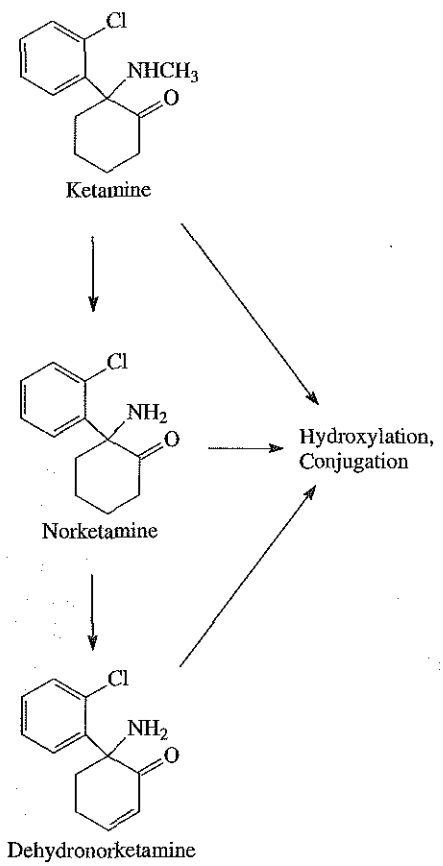

Figure 34-44 Metabolism of ketamine.

viduals are in an amnestic and cataleptic state with eyes open, are able to move limbs involuntarily, and have minimal respiratory or cardiovascular depression. Because some individuals experience acute psychosis and dysphoria during emergence from PCP-induced anesthesia, it was quickly withdrawn from clinical use. Ketamine has about one tenth the potency of PCP, a shorter duration of action, and less prominent emergence reactions, especially in children. Its use in humans is largely limited to pediatrics, but it is widely applied in veterinary medicine.

Most anesthetic agents activate CNS inhibitory $GABA_A$ receptors, glycine-gated Cl^- channel receptors, or nicotinic receptors (acetylcholine-gated Na^+ channels). PCP and ketamine are unique as they act by inhibiting the excitatory glutaminergic system by binding to an *N*-methyl-D-aspartate (NMDA) receptor site to produce noncompetitive allosteric inhibition of glutamate binding.[335] Additional actions include euphoria, elevated blood pressure, tachycardia, and bronchodilation, consequences of inhibition of dopamine and norepinephrine synaptic reuptake. At a higher dose, GABA-ergic and central nicotinic actions may produce sedation, lethargy, coma, and respiratory depression. Additionally, central and peripheral muscarinic and nicotinic response may cause miosis or mydriasis, diaphoresis, increased salivation, bronchorrhea, blurred vision, and urinary retention.

The acronym PCP is derived from the chemical name for PCP, 1-(1-**p**henyl**c**yclohexyl)-**p**iperidine or more colorfully from its designation during the 1960s as the "**p**eace **p**ill". PCP is used recreationally for its mind-altering or "out of body" experience. Adverse effects are complex and unpredictable. In addition to those previously cited, these include dysphoria, ataxia, nystagmus, agitation, anxiety, paranoia, amnesia, seizures, muscle rigidity, hostility, delirium, delusions of grandeur, and hallucinations. A sense of superhuman strength coupled with the lack of pain perception may lead to excessive physical exertion and accidental or intentional self-induced trauma, which in some cases may lead to rhabdomyolysis and myoglobinuric renal failure. Thus PCP-related deaths most often are secondary to these adverse behavioral drug effects. Recreational use of PCP has declined since the 1980s but continues to be a problem in some large metropolitan cities.

With repeated use of PCP, psychological dependence may develop, but tolerance or withdrawal syndrome is not profound.

The drug is rapidly absorbed from the GI tract. This form of ingestion is difficult to regulate and results therefore in the highest probability of overdose or "bad trips." Thus, smoking (PCP sprinkled on tobacco, parsley leaves, or marijuana) is now the most popular mode of ingestion, because users may self-titrate the most dangerous effects of PCP.[487] Once absorbed, PCP is extensively metabolized by the liver (~90% of a dose); only 10% to 15% is excreted unchanged in the urine. The principal metabolites excreted in urine are the glucuronide conjugates of hydroxylated metabolites (~25% to 30%), 5-(1-phenylcyclohexyl-amino) valeric acid (~15%), and unidentified polar metabolites (~40%)[107] (Figure 34-43).[107]

PCP is a lipophilic weak base (pK_a ~8.5). It is secreted into and "trapped" in ionized form in the acidic gastric fluid where concentrations may be 20 to 50 times greater than in serum; subsequently, PCP is reabsorbed in the alkaline duodenum.[487] This gastroenterohepatic recirculation probably contributes to the typical waxing and waning of clinical effects of PCP and, along with its large V_d of 5 to 7 L/kg, partly explains PCP's long elimination $t_{1/2}$ (20 to 50 hours), long duration of action (24 to 48 hours), and prolonged urinary excretion after the last dose (1 to 2 weeks; longer with chronic use).[487]

Treatment of PCP toxicity is supportive. Severe agitation or seizures may respond to diazepam; severe psychoses may require a neuroleptic drug, such as haloperidol.[487] For the most serious cases, continuous nasogastric suction to help remove PCP may be beneficial; urine acidification to hasten elimination has been advocated by some but is controversial.[335]

Ketamine (known on the street as vitamin K, Special K, Super K, cat valium) has become popular as a "club drug" for its PCP- and LSD-like mood altering hallucinogenic effects (referred to as "K-land"), but at higher dose it may cause an "out of body" or "near-death" experience referred to as the "K-hole." Its anesthetic and amnestic properties reportedly have resulted in its use as a date-rape drug.[11] Ketamine is metabolized to norketamine, which has about one third the activity of ketamine, and to dehydronorketamine, which may also be active (Figure 34-44).[31,113]

Analytical Methodology

The initial screening test for PCP is typically immunoassay. For confirmation of a presumptive positive test, a quantitative drug measurement is performed using GC-MS.[158] Immunoassays for ketamine are not available. Ketamine, norketamine, and dehydronorketamine may be determined by GC-MS or LC-MS.[318]

Immunoassay. Quantification of PCP in serum is not helpful in the diagnosis or management of PCP toxicity, because there is low correlation between drug concentration and drug effects.[335] However, qualitative identification of PCP in urine is useful to help diagnose PCP toxicity. For this purpose, PCP-specific immunoassays are rapid and generally are more sensitive than thin-layer chromatography. Whether or not PCP is included in a general urine drug screen depends on applicable regulations and on the prevalence of PCP use in the local community. In some locations, the prevalence of PCP use may be too low to warrant routine screening for PCP. Immunoassays for PCP (e.g., EMIT, FPIA, CEDIA, Roche Abuscreen) are generally reliable; false positives have been reported because of high concentrations of dextromethorphan,[56] diphenhydramine,[272] and thioridazine.[283,466] Confirmation of immunoassay-positive specimens using an alternate technique (e.g., GC-MS) is therefore necessary.

Gas Chromatography-Mass Spectrometry. PCP is required to be included in U.S. government–regulated drug abuse screening programs (see Table 34-8); nongovernmental screening programs may elect to include PCP in drug abuse screens, depending on the local probability of PCP use. Initial screening by immunoassay, if positive, is followed by confirmation using GC-MS. A GC-MS method for PCP is included in the Chapter 34 Appendix that is found on this book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Detection of Drugs of Abuse Using Other Types of Specimens

Urine is currently the most common specimen for detection of drugs of abuse. However, the window of detectability in urine is generally limited to a few days following drug use. In addition, the collection of urine may require some invasion of privacy and loss of dignity, and urine specimens are subject to adulteration or manipulation to evade detection. For these reasons, alternate biological specimens that may avoid some of these limitations have been investigated.[76]

Meconium

Alcohol and drug use during pregnancy is a significant social and medical issue. One study estimated that approximately 11% of women have used illicit drugs during pregnancy[88]; another reported that 15% of the pregnant women studied had used alcohol or illicit drugs.[87] Infants born to mothers who used illicit drugs have an increased rate of perinatal morbidity, mortality, and neurobehavioral problems. Prevention of drug use during pregnancy and proper treatment of drug-exposed infants depend on recognition (detection) of drug use or exposure. Because maternal self-reporting is not reliable, it has been suggested that urine drug testing be performed for high-risk populations as part of standard prenatal care.[100] However, urine testing of the mother or newborn is able to detect only recent drug use (within a few days before birth), and urine collection from newborns may be problematic. For these reasons, Ostrea and co-workers pioneered drug testing using meconium, the fecal material present in the newborn's stool during the first 2 to 3 days, and presented evidence for an improved drug detection rate compared with urine.[342]

Meconium begins to form during the second trimester and continues to accumulate until birth. Drugs are believed to be deposited in meconium via fetal bile excretion and from swallowed amniotic fluid, which contains drug and drug metabolites eliminated in the fetal urine. Testing meconium may therefore provide historical evidence of maternal drug use anytime during the last two trimesters. The greater utility of meconium drug testing compared with urine has been confirmed by others.[74,273,325] Other investigators have suggested that detection limit of the assay is more important than specimen type and that urine test results comparable to meconium will be achieved by lowering the typical screening cutoff for urine testing.[79,120,192,259]

Whereas meconium is more easily collected from newborns than urine, it is considerably more difficult to analyze. Meconium is a heterogeneous, gelatinous material from which drugs must be extracted before analysis by immunoassay and confirmation by GC-MS.[146] It should be noted that drug extraction from meconium using inorganic acids, methanol, or any other alcohol is protected by U.S. patents.[340,341]

Studies on meconium have raised new issues concerning fetal versus maternal drug metabolism. For instance, while *m*-hydroxybenzoylecgonine and *p*-hydroxybenzoylecgonine are present in lesser amounts in adult urine than benzoylecgonine, they are major contributors to the benzoylecgonine immunoreactivity in meconium.[346,427] It is unclear whether these findings represent a difference in fetal cocaine metabolism or are the result of placental transfer of these metabolites. Likewise, concordance between immunoassay screening for marijuana metabolites and GC-MS confirmation for THC-COOH (see Cannabinoids) is considerably less for meconium than for urine, because meconium contains greater amounts of 11-hydroxy-Δ^9-THC and 8β,11-dihydroxy-Δ^9-THC metabolites.[145,146]

As for adult urine, cocaethylene may be detected in meconium, and its presence indicates maternal use of ethanol and cocaine (see section on Cocaine). Significant alcohol use during pregnancy may be indicated by measurement of fatty acid ethyl esters in meconium.[315]

Meconium drug testing is growing but is far less standardized than urine drug testing. Assay cutoff limits and units (ng/g meconium or ng/mL of extract) may vary, and suitable reference or control materials are not yet available. Cutoff limits proposed by SAMHSA are presented in Table 34-9.

Hair

Since the 1970s, hair has been analyzed for trace metals for purposes of assessing nutritional status. However, (1) lack of standardized procedures (collection, preparation, and analysis), (2) lack of reference limits, and (3) problems due to environmental contamination have limited the success of hair analysis for this purpose. However, the analysis of lead, arsenic, and mercury in hair is an established and accepted method of assessing prior toxic exposure to these metals (see Chapter 35).

The analysis of drugs in human hair was described by Baumgartner et al in 1979.[41] Since then, there has been increasing interest in the analysis of hair for the purpose of detecting drug use.[42,190,213,241,243] Hair is advantageous as a biological specimen, because it is easily obtained without loss of privacy or dignity (unless pubic hair is obtained), and it is not easily altered or manipulated to avoid drug detection. Moreover, once deposited in hair, drugs are very stable; therefore prior drug use may be detected for several months. Because hair grows at a relatively constant rate (0.3 to 0.4 mm/d), the potential exists for segmental hair analysis to provide a "chronicle" of prior drug use.

The mechanisms by which drugs are deposited in hair are not well understood but may include transfer from blood to the growing hair shaft, transfer from sweat and sebum (some sweat glands empty into hair follicles), and environmental contamination.[236] Factors that may affect the deposition of drugs in hair also are not well established but may include the rate of hair growth, anatomical location of hair, type of hair, hair color (melanin content), effects of various hair treatments, and environmental contamination, especially for drugs that are smoked (marijuana, cocaine, heroin, and PCP).

Drugs, when deposited in hair, are generally present in relatively low concentrations (pg/mg-ng/mg); thus sensitive analytical techniques are required for detection. Moreover, parent drug is generally present in greater amount than metabolites. Parent drug–specific RIA procedures have most commonly been used for drug detection in hair. Some immunoassays designed primarily for urine drug testing and therefore that may have greatest reactivity with metabolites are of limited use for hair analysis. Confirmation of immunoassay results, generally by GC-MS, GC-MS-MS, or LC-MS-MS, remains a requisite for any forensic application of hair drug testing. These techniques may also be suitable for initial qualitative drug abuse screening[351] and for direct sequential hair analysis without prior immunoassay.[255]

For drug detection, hair offers potential advantages compared with urine, but much additional research will be necessary before hair analysis becomes applied generally. A better understanding of the disposition kinetics of drugs in hair is needed; methods of washing, extraction or digestion, and analysis will all have to be more standardized; cutoff limits will have to be agreed upon; and suitable quality control and proficiency test materials will have to be developed. Toward these goals, SAMHSA has proposed draft drug cutoff values for hair analysis (Table 34-9).

Sweat

Drugs may be excreted in sweat and, as for hair, the parent drug is generally present in a greater amount than metabolites.[213,242] Moreover, sweat excretion may be an important mechanism by which drugs enter hair.[101]

Sweat patch collection devices that resemble an adhesive bandage may be worn for several days to several weeks, during which drug, if present, accumulates in the absorbent pad in the patch while water vapor escapes through the semipermeable covering.[245] Thus sweat drug testing offers the possibility to monitor drug use over extended periods of time without the need for frequent collection of urine.[71] Sweat drug testing would be particularly advantageous for monitoring drug use in correctional institutions or in drug rehabilitation programs.[244] Cutoff values currently proposed by SAMHSA are listed in Table 34-9.

Saliva (Oral Fluid)

The measurement of drugs in saliva is of interest both for purposes of therapeutic drug monitoring and for the detection of illicit drug use.[213,397] Compared with urine, saliva is easy to obtain, with less invasion of privacy and ease of adulteration. Saliva is an ultrafiltrate of plasma; therefore drug concentration in it reflects the free or active fraction and may more closely reflect drug effect than is possible with urine measurements. The transfer of drug from blood to saliva is influenced by drug protein binding, pK_a, lipid solubility, and blood pH (saliva is more acidic than blood). In general, drugs are present in saliva in lower concentration and may be detected for a shorter time period compared with urine.[396,397] Detection of drugs in saliva therefore indicates recent drug use. Moreover, saliva drug concentration may correlate with degree of impairment, except when buccal contamination may have occurred because of oral ingestion, smoking, or snorting of the drug. The SAMHSA draft cutoff values for drugs in saliva are presented in Table 34-9; they have been validated by a large study.[103] (See also Alcohols for a discussion of ethanol measurements in saliva.)

ON-SITE DRUG TESTING

On-site drug test devices for urine and saliva are designed for easy, rugged, and portable use by nontechnical personnel.[336] Although they are relatively simple to use, proper training of nonlaboratory users is important for optimal performance.[169,234,252]

Many on-site devices are commercially available for urine drug testing and at least six for saliva drug testing. They are noninstrumental immunoassay test devices that are designed for use at the site of collection with results available within 3 to ~10 minutes and are variously configured to detect only one drug or as many as 10 drugs simultaneously. The spectrum of drugs tested includes tricyclic antidepressants, barbiturates, benzodiazepines, methadone, MDMA (MDA and MDEA), oxycodone, and the traditional SAMHSA or NIDA 5. As previously cited, such devices are also available for measurement of acetaminophen and salicylate in serum or whole blood. Evaluations for some of these test devices for urine* and saliva[319,362] have been published. A comprehensive review of on-site drug testing is also available.[356] (Also see earlier section on Alcohols for discussion of on-site alcohol testing).

The assay principles of these on-site test devices are briefly summarized with some selected product listings.

Sequential Competitive Binding Microparticle Capture Immunoassay

The Triage (BioSite Diagnostics, San Diego) is an example of a on-site test device that uses a sequential, two-step, competitive binding microparticle capture immunoassay. In this device, drug–colloidal gold microparticles compete with the drug in urine for drug-specific first antibody. The mixture is then transferred onto a membrane that contains an immo-

*References 110, 111, 118, 237, 252, 356, 435, 436, 448, 483, 493.

bilized, drug-specific second antibody. If a drug is present at concentrations above the threshold, the insufficient first antibody is available to combine with all drug–gold particle conjugates. These drug conjugates then bind to an immobilized second antibody to form a colored band, which appears after washing the membrane to remove unbound drug conjugate. If drug is absent or present below threshold concentration, the first antibody combines with all drug–gold particles, which then prevents their subsequent binding to the second antibody. In this case, no colored band is formed. Ligand-conjugated control microparticles and antiligand antibodies are included and the membrane configured to provide both positive internal control (adequate transfer of reagents) and negative internal control (inadequate incubation time).

Homogenous Microparticle Capture Immunochromatography

The underlying principle of one-step, solid-phase immunochromatography (also known as lateral flow immunoassay) is the inhibition of antigen-antibody capture on a porous membrane by a drug present in the specimen. Different applications of this measurement concept have been commercialized.

One approach used by a number of on-site drug testing devices may be characterized as homogenous microparticle capture immunochromatography. In this technique, a drug conjugate is immobilized on the porous membrane and drug-specific antibody, coated on colored microparticles, is present in the specimen application portion of the membrane. When specimen is applied, it moves along the membrane by capillary action; in the process, the antibody-coated microparticles are mobilized.

If drug is present above threshold concentration, the limited antibody binding sites on the colored microparticles are all saturated; these particles cannot react with immobilized drug conjugate and therefore no colored band appears at the test line (positive test). If drug is absent or present below threshold concentration, the microparticles are captured by the immobilized drug conjugate to form a colored band at the test line (negative test). For internal quality control, microparticles not bound at the test line progress to a control line where they are captured by the immobilized antibody (e.g., antimouse or anti BSA if the microparticles are also coated with BSA).

A number of devices are based on this test format including First Check (Worldwide Medical Corp, Irvine, Calif.), microLine (Drug Screening Systems Inc., Blackwood, N.J.), Ontrak TesTcup (Roche Diagnostics, Cherry Hill, N.J.), Verdict (Editek, Inc., Burlington, N.C.), Visualine II (Sun Biomedical Laboratories, Cherry Hill, N.J.), and StarTox (Starplex Scientific, Ontario, Canada).

A variation of the microparticle capture approach is designed to allow visualization of the colored microparticles not captured by the immobilized drug. The intensity of the color, compared with a reference chart, determines test status. This approach is used in the Frontline device (Roche Diagnostics).

Some on-site drug test devices use dye-conjugated, drug-specific antibodies in place of microparticles. Otherwise, test principles are the same as those for the microparticle capture immunoassay. Test devices in this format include AccuSign (Princeton Biomeditech Corp., Princeton, N.J.) and Syva Rapid Test (Dade Behring, Newark, Del.).

Yet another variation reverses the capture configuration. In this case, drug-specific antibody is immobilized on the membrane and the dye-conjugated drug is contained in the application zone. Test principles otherwise remain the same. Examples with this format include Status DS and Status Stik (LifeSign, Somerset, N.J.).

Solid Phase Competitive Sequential Enzyme Immunoassay

A solid phase competitive enzyme immunoassay is used by a number of on-site drug testing devices, including the EZ-Screen (Editek, Inc., Burlington, N.C.), I.D. Block (International Diagnostic Systems Corp., St. Joseph, Mich.), and Target (V-Tech, Inc., Pomona, Calif.). In these devices, drug in urine competes with a drug-enzyme conjugate for a limited number of drug-specific, membrane-immobilized antibody binding sites. After reaction, the membrane is washed to remove unbound drug-enzyme conjugate, and enzyme substrate is added. Because of the competitive nature of the assay, color formation is inversely proportional to urine drug concentration (i.e., higher drug concentrations result in less binding of drug-enzyme conjugate and therefore less color formation).

Latex-Agglutination-Inhibition Immunoassay

The Abuscreen Ontrak (Roche Diagnostic Systems, Branchburg, N.J.) is an example of an on-site device that uses a latex-agglutination-inhibition immunoassay. In this type of assay, drug in urine and drug-latex particle conjugates compete for a limited number of drug-specific antibody binding sites. If drug is absent or below threshold concentration, drug-latex particle conjugates react with antibody and are agglutinated. When the drug is present above threshold, insufficient antibody binding sites are available for reaction with drug-latex conjugates, and their agglutination is thus inhibited.

CHAPTER 35

Toxic Metals

Thomas P. Moyer, Ph.D., Mary F. Burritt, Ph.D., and John Butz, B.A.

Metals have been recognized as toxins for centuries. Arsenic poisoning was a favored way to dethrone royalty in the Renaissance era. Mercury poisoning was common in eighteenth century Europe associated with generation of felt from beaver pelts to make the popular top hat. The hat makers displayed behavioral changes typical of those resulting from mercury exposure, leading to common use of the phrase "mad as a hatter." In the 1950s a tragic case of mercury poisoning occurred in the Minamata Bay of Japan where large quantities of industrial mercury were dumped into the bay. Over 3000 victims have been recognized as having "Minamata disease," a syndrome that is characterized by symptoms of methylmercury poisoning.[59] In 1971 mercury contamination of seed grain caused 6000 deaths in Iraq.

BASIC CONCEPTS

Important questions to consider for metal toxicity are: (1) Is the metal of concern toxic? (2) What is the prevalence associated with the metal of concern? (3) What are the signs and symptoms of exposure to that metal? (4) Is the degree of exposure known? (5) Do adequate analytical techniques exist to measure the metal? (6) Are appropriate tissues available to quantify the metal?

Section I of this chapter addresses these questions. Section II focuses on the unique characteristics of the more common metals known to be associated with toxicity. Readers are referred to Casarett's and Doull's *Toxicology*[96] for detail on rare metal toxicities.

PREVALENCE OF METAL-BASED TOXICITY

As the twenty-first century begins, one would expect that metal toxicities would be well known and avoidable. However, humans encounter elemental toxins frequently, with chronic, low-concentration exposure occurring more frequently in individuals than in large population groups. Concern continues regarding low-concentration exposure to lead and the effect such exposure has on mental development in the young. Arsenic is common in our environment, and individuals are occasionally exposed because of a lack of knowledge of the household products they are using. Many insecticides contain arsenic as an active ingredient; careless use of these products can lead to significant exposure. Arsenic is frequently identified as the cause of peripheral neuropathy among patients who have been unsuspectingly exposed. Ground water contaminated with arsenic in the Bengal basin of Bangladesh exceeding WHO safety limits because of leaching from bedrock presents a serious health risk to the large population living in that region.* Cadmium is used to manufacture brightly colored paint pigments; painters who fail to use adequate respiratory protection while spray painting with these products can experience significant exposure. Cadmium is also a significant toxin in tobacco products.[81] Mercury has been shown to leach from dental amalgams.[137] Initially, this finding caused considerable concern; however, later studies have failed to find a causal relationship.[6,78,172] Studies have indicated that apoptotic pathways are initiated by metals such as arsenic, cadmium, chromium, nickel, and beryllium and possibly lead, antimony, and cobalt.[135]

Although rare, manufacturing errors can cause production of products that contain toxic metals. In the early 1960s, a Canadian beer brewery accidentally contaminated a large lot of its product with cobalt. The product was sold to and consumed by the public, resulting in an outbreak of renal disease and cardiomyopathy. In this type of situation, the U.S. Public Health Service is often called in to identify the cause of an outbreak of unusual symptoms. The clinical laboratory should be prepared to support these types of investigations.

*References 1, 15, 86, 89, 93, 154, 166, 173.

One study of a large outpatient general medicine population ($N = 329,000$) places perspective on the issue of the role of toxic metals in disease.[118] From among a group of human subjects representing a broad spectrum of all disease types, with some concentration of tertiary care patients, 1986 patients (0.6% of the total population) were identified as having some physical finding or exposure concern indicating reason for further examination for metals. Of these, 152 cases (0.05% of the original population) were singled out by laboratory testing as cases of high suspicion that metals were involved. Of these, 32 cases (0.01% of the population, or 1 in 9700) ultimately were proven to have metal toxicities. Eighteen of these cases were arsenic related, two were cadmium related, seven were lead related, and five were mercury related.

The incidence of metal poisoning in this population attributable to arsenic, cadmium, lead, or mercury poisoning appears to be of the same scale as the more common inborn errors of metabolism, such as neonatal hypothyroidism and phenylketonuria, and is the same order of magnitude as the incidence of adult-onset hemochromatosis, a disease for which mandatory screening has been suggested. Screening for these diseases is indicated because they are treatable, and treatment significantly reduces long-term morbidity. The same can be said for metal toxicities. When identified early, disease caused by metal exposure is readily treatable with good outcome. Conversely, if exposure is not identified and reduced, serious and sometimes irreparable damage to the nervous, renal, and cardiovascular systems can occur.

TABLE 35-1 Conditions in Which Metal Toxicity Can Be a Causative Factor

Metal	Condition
Aluminum	In dialysis encephalopathy or dementia
Arsenic	When the patient reports bilateral pain radiating from feet to leg
Cadmium	Renal disease in aerosol painters
Copper-zinc deficiency	Induced loss of wound healing
Lead	In children under age 2 living in older homes
Manganese	Onset of parkinsonism under age 50
Mercury	Acute changes in behavior, impaired speech, visual field constriction, hearing loss, and somatosensory
Selenium (deficiency)	In patients undergoing total parenteral nutrition
Thallium	Acute hair loss
Zinc (deficiency)	Burn patients exhibiting erythema

Diagnosing Toxicity

Confirming the diagnosis of metal toxicity is difficult because signs and symptoms are similar to a number of other diseases. Diagnosis of metal toxicity requires demonstration of all of the following three factors: (1) a source of metal exposure must be evident, (2) the patient must demonstrate signs and symptoms typical of the metal, and (3) abnormal metal concentration in the appropriate tissue must be evident.

If one of these features is absent, one cannot make a conclusive diagnosis of metal toxicity. The laboratory plays a key role in this process, and appropriate specimen collection coupled with accurate analysis can make a major difference in correct diagnosis.

In clinical practice, analysis of toxic elements should always be considered in the clinical workup of the patient with (1) renal disease of unexplained origin, (2) bilateral peripheral neuropathy, (3) acute changes in mental function, (4) acute inflammation of the nasal or laryngeal epithelium, or (5) a history of exposure. Certain elements should be considered as the active, causative, or deficient agent in specific circumstances (Table 35-1).

Classification of Metals

Some metals are essential for life (see Chapter 30), but if an individual's exposure exceeds a certain threshold, toxicity may develop. Nonessential metals can be toxic even at low concentrations. Review of the periodic table provides some insight into the determination of a metal's potential toxicity (Figure 35-1).

Elements in groups IA and IIA in rows three through five of the periodic table generally fit the role of essential elements. The gastrointestinal tract and dermis are very effective at regulating the body burden of these compounds—it is very difficult to cause toxicity by one of these elements unless the element is injected directly into the vascular system. Elements in groups IB through VIIB and VIII in row four of the periodic table are generally essential for life but required at low concentrations; many are protein cofactors required for activity. The gastrointestinal tract and dermis regulate intake to some degree, but overload will induce passive diffusion that can lead to excessive concentrations and toxicity. Elements in row five and below are classified as nonessential (or if essential, are required at picomolar concentrations or less). As one moves from right to left across the periodic table, the elements become more prevalent and therefore have greater potential to induce toxicity. Elements in groups IB and IIB in rows six and seven and group IIIA through VIA in rows four to six are of particular interest as toxins, because they have electron configuration that allows them to bond covalently with sulfur. Later in this chapter, this characteristic is identified as a significant factor in the

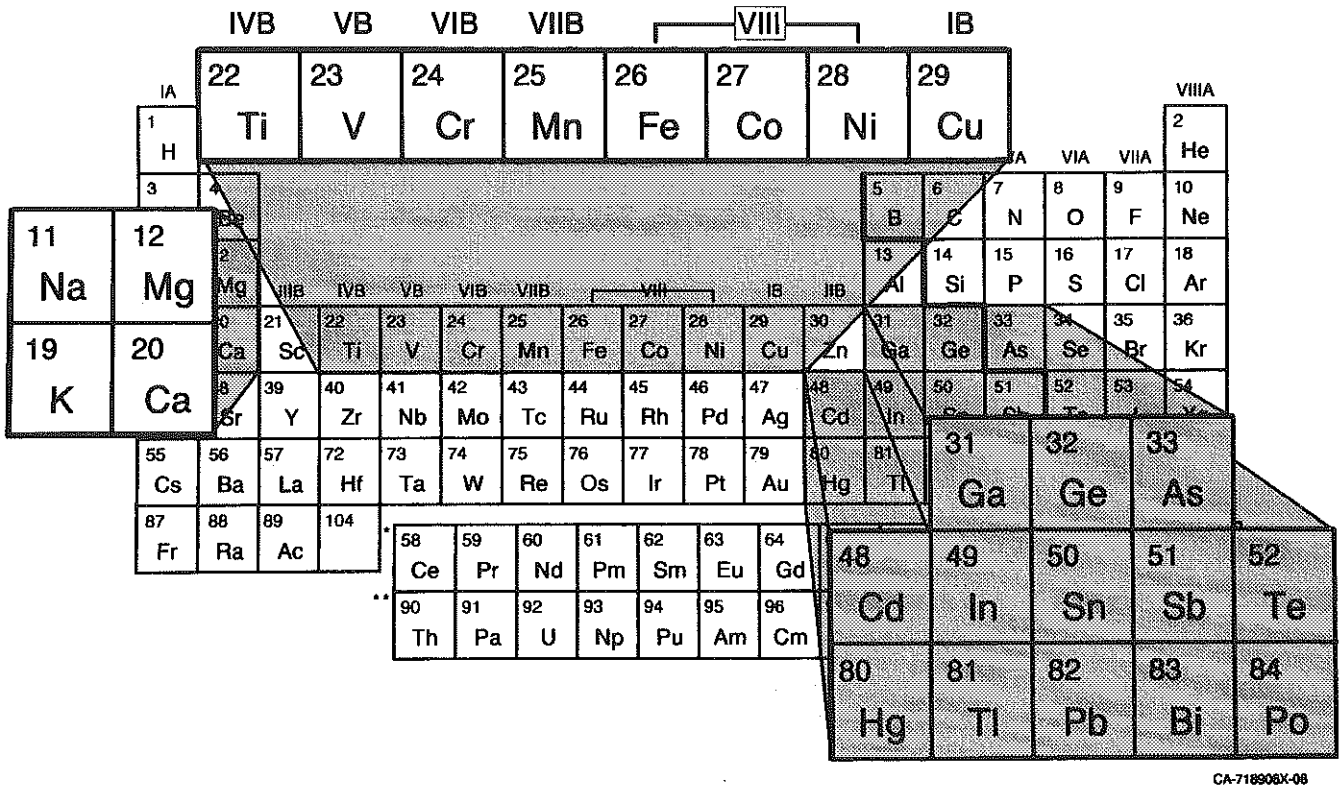

Figure 35-1 Periodic table, with emphasis on toxic elements.

mechanism of action of the group of metals often referred to as "heavy metals."* These include arsenic, cadmium, lead, mercury, and thallium, all toxins of considerable concern. Elements in VIIA (halides) are essential for life but toxic when present in excess. Group VIIIA, the inert elements, are toxic in the gas phase because they can cause anoxia; their inert characteristic is the cause of their toxicity.

Occupational Monitoring

Employees are frequently monitored when working in an environment where exposure to toxic metals is a possibility.† The most common form of monitoring involves quantification of airborne concentrations of metals in the production process. Threshold limit values for airborne concentrations and time-interval exposure concentrations are defined by the U.S. National Institute for Occupational Safety and Health (NIOSH) to ensure worker safety. Workers may also be monitored by quantification of biological samples. The most common sample used is a random urine sample, and results are expressed in concentration units for the metal of interest per gram of creatinine to normalize for excretion volume variances. Only cadmium has defined urine excretion concentrations set by a U.S. federal agency to ensure worker safety.[127] Additional technical and regulatory information about toxic metals is available at the Occupational Safety and Health Administration (OSHA) web site (http://www.osha.gov/SLTC/metalsheavy/index.html).

The World Health Organization (WHO) and OSHA have defined blood concentrations for lead that are designed to warn employers when workers are overexposed.[143] Safety limits for other metals have been set by professional organizations, such as the American Conference of Governmental Hygienists.[53]

Analytical Methods

Atomic absorption spectrometry with flame (AA-F) or electrothermal atomization furnace (AA-ETA), inductively coupled plasma-emission spectroscopy (ICP-ES), inductively coupled plasma-mass spectrometry (ICP-MS), and high-performance liquid chromatography-mass spectrometry (LC-MS) are state-of-the-art analytical techniques used to measure metals in biological fluids. They are specific and sensitive and provide the clinical laboratory with the capability to measure a broad array of metals at clinically significant concentrations. For example, ICP-MS is used to measure several metals simultaneously.[26,113,124] Photometric assays are also available but require large volumes of sample and have limited analytical performance. Spot tests are also

*The International Union of Pure and Applied Chemistry (IUPAC) considers the term "heavy metal" to be both meaningless and misleading, and recommends that it no longer be used. (Duffus, JH. "Heavy metals" a meaningless term? IUPAC Technical Report. Pure Appl Chem 2002;74:793-807.)

†References 22, 25, 41, 75, 90, 149, 182.

available but should be considered obsolete because they are error prone, often yielding false-positive results.[133]

SPECIFIC METALS

Certain metals are known to be toxic when humans are exposed to elevated concentrations and five metals are listed in the top 20 of the 2003 CERCLA* Priority List of Hazardous Substances (http://www.atsdr.cdc.gov/cxcx3.html). They include arsenic (No. 1), lead (No. 2), mercury (No. 3), cadmium (No. 7), and chromium (No. 17). Other metals of concern include aluminum, beryllium, cobalt, copper, iron, manganese, nickel, platinum, selenium, silicon, silver, and thallium. The Agency for Toxic Substances and Disease Registry (ATSDR) produces "toxicological profiles" for many of these metals on their website (http://www.atsdr.cdc.gov/toxpro2.html). These hazardous substances are ranked based on their frequency of occurrence, toxicity, and potential for human exposure.

Several of these metals are also considered essential trace elements and are discussed also in Chapter 30. Risk assessments for essentiality versus toxicity for chromium, copper, iodine, iron, manganese, molybdenum, selenium, and zinc have been performed by several U.S. governmental and private organizations.[72]

Methods for aluminum, arsenic, lead, mercury, and selenium are included in the Appendix to Chapter 35 located on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

ALUMINUM

Aluminum (Al) is an extremely light, whitish, lustrous, metallic element, obtainable from bauxite or clay. Aluminum compounds are used chiefly for their antacid and astringent properties. In 1972 Alfrey and colleagues first described an encephalopathy that was observed in patients undergoing prolonged hemodialysis for renal failure.[2] The disease was characterized by abnormal speech, myoclonic jerks, and convulsions. Patients with these signs also showed a predominance of osteomalacic fractures.[178] Since then, it has become well understood that exposure of patients in renal failure to Al-laden dialysis water, Al-containing oral phosphate binders, and Al-laden albumin administered during dialysis is the primary cause of these signs of Al toxicity. Aluminum is also a developmental toxicant if administered parenterally.[54]

Under normal physiological conditions, the usual daily dietary intake of 5 to 10 mg of Al is completely excreted. This excretion is accomplished by avid filtration of Al from the blood by the glomerulus of the kidney. Patients in renal failure lose this ability and are candidates for Al toxicity. The dialysis process is not highly effective at eliminating Al and can be a significant source of exposure.[3] Furthermore, it is a common practice to administer Al-based gels orally to patients in renal failure to reduce the amount of phosphate absorbed from their diet to avoid excessive phosphate accumulation. A small fraction of this Al may be absorbed; patients in renal failure accumulate this Al. Following dialysis, albumin may be administered to replace that which is removed during dialysis. Some albumin products have high Al content resulting from the pharmaceutical purification process of passing the product through Al silicate filters.

Aluminum accumulates in blood if not filtered by the kidney; it avidly binds to proteins, such as transferrin, and is rapidly distributed throughout the body. Aluminum overload leads to the accumulation of Al at two sites: in bone[27] and in the brain.[58] In bone, Al replaces calcium at the mineralization front, disrupting normal osteoid formation. This can be readily visualized histologically using Goldner's stain. Deposition of Al in bone interrupts normal calcium exchange; the calcium in bone becomes unavailable for resorption into blood, a process under the physiological control of parathyroid hormone (PTH) and 1,25 dihydroxy vitamin D. Aluminum binding to calcium binding sites in the parathyroid gland causes an abnormal physiological response by the parathyroid gland, which results in the biochemical profile that is virtually diagnostic of Al overload disease—abnormally low PTH for the degree of renal failure present combined with high serum Al.[110]

The normal physiological action of PTH on bone is blunted in patients with renal failure, because their renal cells are not synthesizing the 1,25 dihydroxy vitamin D required for normal PTH action. It is typical for patients in renal failure to have high serum PTH values; this represents secondary hyperparathyroidism, the normal physiological response to vitamin D deficit. Deposition of Al at the bone mineralization front and binding to parathyroid calcium receptors interferes with this physiologic process. The usual parathyroid response to these conditions decreases secretion of PTH. The result is lower-than-expected serum PTH concentration for the degree of renal disease present.

McCarthy has defined a biochemical profile that is characteristic of Al overload disease.[110] In human subjects with normal renal function, serum Al concentration is normally lower than 6 μg/L. Patients in renal failure invariably have serum Al concentrations well above this amount. Clinical guidelines published in 2003[57] suggest that patients with no signs or symptoms of osteomalacia or encephalopathy are likely to have serum Al concentrations <20 μg/L and PTH whole molecule concentrations >16 pmol/L, typical for secondary hyperparathyroidism associated with renal failure. Patients with signs and symptoms of osteomalacia or encephalopathy typically have serum Al concentrations >60 μg/L and PTH concentrations lower than <16 pmol/L; these laboratory parameters indicate Al-related bone disease. Patients with serum Al concentrations >20 μg/L but <60 μg/L were identified as candidates for likely onset of Al-related bone disease; these patients required aggressive efforts to reduce their daily Al exposure. A graphic presentation of these concepts is presented in Figure 35-2. Efforts to reduce

*CERCLA: Comprehensive Environmental Response, Compensation, and Liability Act (or Superfund).

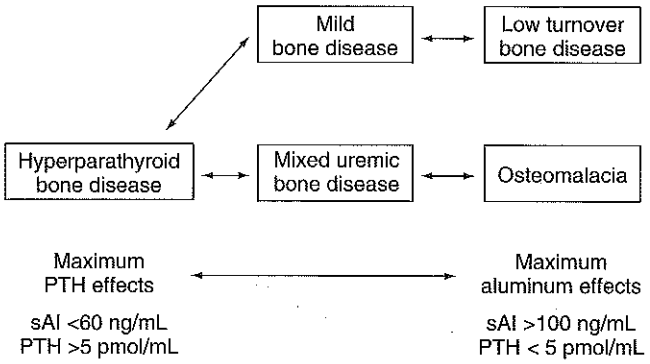

Figure 35-2 Aluminum's effect on bone physiology.

Al intake include switching from Al-containing phosphate binders to calcium-containing phosphate binders, ensuring that dialysis water contains less than 10 μg/L of Al, and ensuring that the albumin used during postdialysis therapy is Al-free.

Aluminum toxicity has also been linked with oral exposure as a result of Al-containing pharmaceutical products such as Al-based phosphate binders or antacid intake.[138] As over-the-counter antacids are an important source for human Al exposure from a quantitative point of view, patient information leaflets in Europe contain warnings of possible Al toxicity.[138]

Interest in the role of Al in Alzheimer's disease (AD) was raised when Perl observed that Al accumulates in the neurofibrillary tangle of patients with AD.[129] He concluded that the focal accumulation of Al had an association with neurofibrillary degeneration in the hippocampal neurons that might play a role in the development of AD. Although a cause-and-effect relationship between accumulation of Al in brain and AD has yet to be conclusively demonstrated,[142] studies have clearly shown an increased concentration of Al in the brain.[30,85,151] It is possible that accumulation of Al in the neurofibrillary tangle of AD patients is a secondary finding associated with the disease but not directly related to the cause. Glycosylation of beta amyloid likely plays a role in AD and may provide for structural alteration of protein that increases Al binding.[61,85] A 2002 review discusses the role of Al as a risk factor for developing Alzheimer's disease.[162]

Aluminum-related bone disease can be diagnosed and treated with deferoxamine, an avid chelator of both iron and Al. The deferoxamine infusion test is useful for the ultimate diagnosis of Al overload disease, and the drug has demonstrated utility for treating acute Al overload.[50,57,114]

Collection of specimens for serum Al analysis can be a complicating factor. Most of the common evacuated blood collection devices used in phlebotomy today have rubber stoppers that are made of Al silicate. Puncture of the rubber stopper for blood collection is sufficient to contaminate the sample with Al to produce an abnormal concentration of Al. Typically, blood collected in standard evacuated blood tubes will be contaminated by 20 to 60 μg/L of Al; this can be readily demonstrated by collecting blood from a normal volunteer into a standard evacuated phlebotomy tube. Special evacuated blood collection tubes are required for Al testing.[116] These tubes are readily available from commercial suppliers and should always be used. Failure to pay attention to this issue can result in the generation of abnormal results because of sample contamination, which can lead to misinterpretation and misdiagnosis.

Analysis of Al can be routinely performed by inductively coupled plasma (ICP) mass spectrometry (ICP-MS). Alternatively, atomic absorption spectrometry with electrothermal atomization may be employed, but considerable attention must be paid to matrix interferences.

Antimony

Antimony (Sb) compounds have been known since ancient Egyptian times and were used as cosmetics by the women of that era. In the sixteenth century, Sb preparations were thought to be wonder drugs and in the nineteenth century were prescribed for a number of conditions. Antimony compounds are used today as the standard treatment against parasitic diseases, such as leishmaniasis, schistosomiasis, and bilharziasis.[32]

Pure metallic Sb is not used in industry because it is very brittle; however, alloys of Sb are used in a number of fields of technology. For example, addition of Sb to lead, tin, and copper increases the hardness of these metals when used as electrodes, bullets, type metal for printing, and ball bearings. Other uses include fire-resistant chemicals, pigments, and dyes.

Antimony is not an essential metal. Workplace exposure to Sb dust over a period of years leads to pneumoconiosis. The size of the dust particles of Sb trioxide significantly increases the occurrence of pneumoconiosis, with the smaller particles being more dangerous. The workers at greatest danger are those in underground facilities and metal production. Smoking may also contribute to the respiratory problems.[10] Symptoms of acute exposure include a metallic taste, headache, nausea, and dizziness; after a short interval, vomiting, diarrhea, and intestinal spasms occur. The severity of the symptoms depends on both the dose and route of administration. In chronic intoxication, adverse health effects include cardiac arrhythmias, upper respiratory and ocular irritation, spontaneous abortions, premature births, and dermatitis.[51] Lymphocytosis, eosinophilia, and a reduction in leukocyte and platelet counts are also seen and indicate damage to the liver and spleen. The inability of the blood to clot is seen when a lethal dose of Sb is received. Breathing is shallow and irregular, and death is almost always due to respiratory paralysis.[9] There is evidence supporting an increased risk for the development of lung cancer in Sb smelter workers, but the effect may be multifactorial due, for example, to the presence of arsenic in the work environment.[10,44] It is important to remember that when intoxication occurs with metallic Sb, the effect is due not just to the

Sb, but also the lead, arsenic, and other metals that may accompany it.[9]

Arsenic

Arsenic (As) is perhaps the best known of the metal toxins, having gained notoriety from its extensive use by Renaissance nobility as an antisyphilitic agent and an antidote against acute arsenic poisoning, as chronic administration of low doses protects against acute poisoning by massive doses.[130] This agent was memorably used in the well-known tale "Arsenic and Old Lace"[92] as a means of terminating undesirable acquaintances. Even today, As is still a dangerous toxicant as evidenced by the Bangladesh incidence where several hundred persons had been poisoned by drinking ground water contaminated with As leaching from bedrock.* In fact, as mentioned earlier, arsenic is listed as the No. 1 toxicant on the U.S. CERCLA Priority List of Hazardous Substances (http://www.atsdr.cdc.gov/cxcx3.html). It is also still found in some insecticides.

Arsenic exists in a number of toxic and nontoxic forms.[165] The toxic forms are the inorganic species As^{3+}, also denoted as As(III), the more toxic As^{5+}, also known as As(V), and their partially detoxified metabolites, monomethylarsine (MMA) and dimethylarsine (DMA). Detoxification occurs in the liver as As^{5+} is reduced to As^{3+} and then methylated to MMA and DMA.[186] As a result of these detoxification steps, As^{3+} and As^{5+} are found in the urine shortly after ingestion, whereas MMA and DMA are the species that predominate more than 24 hours after ingestion. Urinary As^{3+} and As^{5+} concentrations peak at approximately 10 hours and return to normal 20 to 30 hours after ingestion. Urinary MMA and DMA concentrations normally peak at about 40 to 60 hours and return to baseline 6 to 20 days after ingestion.[117] The half-life of inorganic As in blood is 4 to 6 hours with a half-life of the methylated metabolites of 20 to 30 hours. Serum concentrations of As are elevated for only a short time after administration, after which As rapidly disappears into the large body phosphate pool. Abnormal serum As concentrations are detected for only a few hours (<4 hours) after ingestion. The structures of these and related As species are shown in Figure 35-3.

Nontoxic forms of As are present in many foods. Arsenobetaine and arsenocholine are the two most common forms of organic As that are found in food.[99] The foods that most commonly contain significant concentrations of organic As are shellfish and other predators in the seafood chain (e.g., cod and haddock). Consequently the rate of As excretion in normal people is 0 to 120 μg per 24-hour specimen. Following ingestion, arsenobetaine and arsenocholine undergo rapid renal clearance to become concentrated in the urine. Organic As is completely excreted within 1 to 2 days after ingestion, and there are no residual toxic metabolites. The apparent half-life of organic As is 4 to 6 hours. Consumption of seafood before collection of a urine sample for As testing is likely to result in an elevation of the concentration of As reported to be found in the urine; this can be clinically misleading.

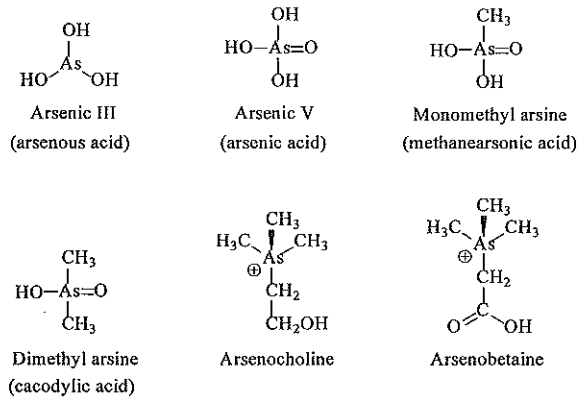

Figure 35-3 Structures of arsenic species.

The toxicity of As is due to three different mechanisms, two of which are related to energy transfer. Arsenic avidly binds to dihydrolipoic acid, a necessary cofactor for pyruvate dehydrogenase. Absence of the cofactor inhibits the conversion of pyruvate to acetyl coenzyme A, the first step in gluconeogenesis. Arsenic also competes with phosphate for reaction with ADP, resulting in formation of the lower energy ADPAs rather than ATP. Arsenic also binds with any hydrated sulfhydryl group on protein, distorting the three-dimensional configuration of the protein and thus causing it to lose activity. Arsenic is also a known carcinogen, but the mechanism of this effect is not definitively known.[37] British antilewisite (BAL) is an effective antidote for treating As intoxication; the active agent in BAL is dimercaprol, a sulfhydryl-reducing agent. This suggests that the primary mechanism of action of As's toxicity is related to sulfhydryl binding. Arsenic also interferes with the activity of several enzymes of the heme biosynthetic pathway.[68] There is also evidence of an increased risk of bladder, skin, and lung cancers following consumption of water with high As contamination[18,145] and lung cancer from smoking. In addition, a causal association has been established between exposure to environmental tobacco smoke and lung cancer, with a relative risk in the order of 1.2.[18,120]

To distinguish among toxic inorganic species and nontoxic organic species of As of seafood origin, high-performance liquid chromatographic (HPLC) techniques that separate the various species of As in biological fluids and tissues have been developed.[158] A relatively simple method of separation using liquid-liquid extraction has also been reported.[7] A typical finding in a urine specimen with total 24-hour excretion of As of 350 μg/24 hours is that greater than 95% is present as the organic, nontoxic seafood species and that less than 5% is present as the inorganic, toxic species. Such a finding indicates that the elevated total As concentration was likely due to ingestion of seafood.

*References 1, 15, 86, 89, 93, 154, 166, 173.

Hair analysis is frequently used to document time of As exposure.[83] Arsenic circulating in the blood will bind to protein by formation of a covalent complex with sulfhydryl groups of the amino acid cysteine. Because As has a high affinity for keratin, which has high cysteine content, the As concentration in hair or nails is higher than in other tissue. Several weeks after exposure, transverse white striae, called "Mees' lines," may appear in the fingernails; this is caused by denaturation of keratin by metals such as As, cadmium, lead, and mercury. Because hair grows at a rate of approximately 0.5 cm/mo, hair collected from the nape of the neck can be used to document recent exposure. Axillary or pubic hair is used to document long-term (6 months to 1 year) exposure. Hair As >1 μg/g dry weight indicates excessive exposure. In one study, the highest hair As observed was 210 μg/g dry weight in a case of chronic exposure that was the cause of death.[83]

Serum is the least useful specimen for identifying As exposure. Serum concentrations of As are elevated for only a short time after administration, after which As is bound to protein[187] and rapidly disappears into the large body phosphate pool, as the body treats As like phosphate, incorporating it wherever phosphate would be incorporated. Absorbed As is rapidly circulated and distributed into tissue storage sites. Abnormal serum As concentrations are detected for only a few hours (<4 hours) after ingestion. This test is useful only to document an acute exposure when the As is likely to be >100 ng/mL for a short period of time. Normally, serum As is <35 ng/mL.

Arsenic also has been accurately analyzed by ICP/MS.[26,124] The specimen is prepared in dilute acid containing gallium as an internal standard and aspirated directly into the argon plasma. Mass response from the argon plasma is monitored for As (75 m/z), gallium (70 m/z), and $^{16}O^{35}Cl$ (51 m/z) to allow for correction for $^{40}Ar^{35}Cl$ (75 m/z) interference. The operator must be aware of the potential for interference from argon chloride. A correction is made by accounting for chloride by measuring 51 m/z and subtracting that residual from 75 m/z.[124] Urine is the sample of choice for As analysis because As is excreted predominantly by the kidney where it becomes concentrated. An ICP-MS method for quantifying As in urine is included in the appendix for this chapter, which is found on the book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/). Atomic absorption methods are also available.[7]

Beryllium

Beryllium (Be) is an alkaline earth metal found in the earth's crust at an approximate concentration of 3 to 5 mg/kg; it is poisonous and not necessary for human health. Beryllium alloys are lightweight, stiff, and highly electrically conductive. Beryllium as pure metal, Be alloys, and ceramics are used in a wide range of applications, including dental appliances, golf clubs, nonsparking tools, wheelchairs, satellite and spacecraft manufacture, circuit board production, and nuclear power, and in weapons as a neutron modulator.

The general population is exposed to Be through food and drinking water although the concentrations are low and of no clinical consequence. The major route by which Be enters the body is via the respiratory tract, and industrial exposure usually occurs from inhalation and ingestion of Be dust. Inhaled Be compounds are cleared very slowly from the lungs. Soluble compounds are absorbed to a much greater degree than those such as Be oxide, which are much less soluble. Beryllium salts are strongly acidic when dissolved in water and this is thought to be a major toxic effect on human tissue. Absorbed Be accumulate in the skeleton. Renal clearance is very slow. Beryllium can inhibit a variety of enzyme systems including alkaline phosphatase, acid phosphatase, phosphoglycerate mutase, hexokinase, and lactate dehydrogenase.[144]

Acute exposure is rare, usually caused by an industrial accident or explosion, and typically results in chemical pneumonitis. Chronic Be exposure in the workplace has led to occupational health concerns because of its potential to cause a progressive and potentially fatal respiratory condition called chronic Be disease (CBD) characterized by the formation of granulomas resulting from an immune reaction to Be particles in the lung.[49] Studies have suggested that the size of the Be particles affects not only the site of deposition but also the amount deposited. This in turn may influence the clearance rate and thus the time of contact between the immune cells and Be.[97] Several years ago, researchers noted that blood and lung cells from CBD patients proliferated when exposed to Be in culture. This assay has been refined and is offered as the Be lymphocyte proliferation test (BeLPT). Unfortunately, because of the nature of the test and the variability from lab to lab, the BeLPT can produce false-negative and problematic results.[49,108] Efforts have begun by several groups to standardize the assay. Despite these issues, the BeLPT in bronchoalveolar cells is part of the current "gold standard" diagnosis for CBD.[144] The clinical course of chronic Be disease is variable and the prognosis is unpredictable. Studies suggest, but do not conclusively link, Be exposure and lung cancer in humans.[73]

Cadmium

Cadmium (Cd) is a byproduct of zinc and lead smelting. It is used in industry in electroplating, in the production of nickel-based rechargeable batteries, as a common pigment in organic-based paints, and in tobacco products. Breathing the fumes of Cd vapors leads to nasal epithelial deterioration and pulmonary congestion resembling chronic emphysema.[81] A common source of chronic exposure is spray painting of organic-based paints without the use of a protective breathing apparatus. Auto repair mechanics represent a work group that has significant opportunity for exposure to Cd.

The toxicity of Cd resembles the other metals (arsenic, mercury, and lead) in that it attacks the kidney; renal

dysfunction with proteinuria of slow onset (over a period of years) is the typical presentation.[63,150] Chronic exposure to Cd causes accumulated renal damage.[150] Breathing the fumes of Cd vapors leads to nasal epithelial deterioration and pulmonary congestion resembling chronic emphysema. Cadmium toxicity is expressed via formation of protein-Cd adducts that change the conformational structure of the protein, causing it to denature. This protein denaturation occurs at the site of highest concentration—in the alveoli if exposure is due to dust inhalation and in the proximal tubule of the kidney, because this is a major route of excretion.

In 1992 the NIOSH mandated that employees exposed to Cd in the workplace be monitored using the quantification of urine Cd and creatinine, expressing the results of μg of Cd per gram of creatinine.[127] This is based on the finding that renal damage caused by Cd exposure can be detected by increased Cd excretion relative to creatinine. Cadmium excretion >3 μg Cd/g of creatinine indicates significant exposure to Cd. Results >15 μg Cd/g of creatinine are considered indicative of severe exposure. Urine Cd is a more specific measure of Cd exposure than are other markers of renal function, such as β_2-microglobulin, retinol-binding protein, or *N*-acetyl glucosaminidase.[174]

Normal blood Cd concentration is less than 5 ng/mL, with most concentrations being in the interval of 0.5 to 2 ng/mL. Moderately increased blood Cd (3 to 7 ng/mL) may be associated with tobacco use.[80] Acute toxicity is observed when the blood concentration exceeds 50 ng/mL. Usual daily excretion of Cd is less than 3 μg/day. Collection of urine samples using a rubber catheter can result in elevated results, because rubber contains trace amounts of Cd that are extracted as urine passes through it. Brightly colored plastic urine collection containers should be avoided because the pigment in the plastic may be Cd-based. Cadmium concentrations also increase with age and may be involved with senescence.[16] Cadmium is usually quantified by atomic absorption spectrometry, but it can also be accurately quantified by ICP-MS.[124]

Chromium

Occupational exposure to chromium (Cr) represents a significant health hazard.[5,126] Chromium is used extensively in the manufacture of stainless steel, in chrome plating, in the tanning of leather, as a dye for printing and textile manufacture, as a cleaning solution, and as an anticorrosive in cooling systems. The toxic form of Cr is Cr^{6+} (Cr[VI]), which is quite rare; a strong oxidizing environment is required to convert the common form Cr^{3+} (Cr[III]) to Cr^{6+}, as might be found when Cr^{3+} is exposed to high temperatures in the presence of oxygen or during high-voltage electroplating. Inhalation of the vapors of Cr^{6+} causes erosion of the epithelium of the nasal passages and produces squamous-cell carcinomas of the lung.[40,126] Cr^{6+} is very lipid soluble and readily crosses cell membranes, whereas Cr^{3+} is rather insoluble and does not readily cross membranes. Clinically, monitoring biological specimens for Cr^{6+} is neither practical nor clinically useful to detect Cr toxicity, as the instant it enters a cell, it is reduced to nontoxic Cr^{3+}.[169] Instead, monitoring the air at the manufacturing site for Cr^{6+} is the usual way to test for Cr^{6+} exposure. Quantification of total Cr in urine can be used to assess exposure to total Cr but does not indicate that the specific exposure was to Cr^{6+}. Atomic absorption spectrometry is commonly used to measure Cr concentrations in body fluids.[152]

Chromium has also been known as the "glucose tolerance factor." Chromium is required for insulin activity.[115] Work from the 1970s suggested Cr deficiency as a cause of diabetes, but this theory has been refuted as an artifact of specimen collection anomalies.[24] A 1994 study demonstrated that Cr concentrations in normoglycemic subjects are essentially the same as those in hypoglycemic subjects.[95] Existing technology cannot measure Cr deficiency, because the lower limit of the reference interval of Cr in blood challenges the detection limit (0.2 ng/mL) of atomic absorption techniques.

Cobalt

Cobalt (Co) is rare but widely distributed in the environment. Cobalt is an essential element, although Co deficiency has not been reported in humans. Cobalt is the essential cofactor in vitamin B_{12}. Quantification of active vitamin B_{12} (see Chapter 30) is the usual way to assess nutritional status; quantification of serum, blood, or urine Co concentration is not the typical means of assessing vitamin B_{12} status.

Cobalt is found in metal alloys that (1) are very hard, (2) have high melting points, and (3) are resistant to oxidation.[47,102] Occupational exposure occurs during production and machining of these metal alloys and can lead to interstitial lung disease.[121] Cardiomyopathy and renal failure are symptomatic of acute Co exposure; this was exemplified by an incidence of mass population exposure to Co when beer contaminated with the metal was consumed.[163] Quantification of urinary Co is an effective means of identifying individuals with excessive exposure.

Cobalt is not highly toxic, but large enough doses will produce pulmonary edema, allergy, nausea, vomiting, hemorrhage, and renal failure. Chronic symptoms include pulmonary syndrome, skin irritation, allergy, gastrointestinal irritations, nausea, cardiomyopathy, hematological disorders, and thyroid abnormalities.[100] The inhalation of dust during machining of Co alloyed metals can lead to interstitial lung disease.[121] Improperly handled, ^{60}Co can cause radiation poisoning from exposure to gamma radiation. Cobalt exposure alone may not lead to toxicity and must be considered within the context of exposure to multiple metals.[102]

Cobalt is quantified in biological tissues by atomic absorption spectrometry[157] and by ICP-MS.[26]

Copper

The homeostasis and analysis of copper (Cu) are discussed in Chapter 30. Copper ingestion has been found to lead to

serious toxicity,[66,79] and it may be encountered as a pesticide. Also, Cu is one of the active agents in marine antifouling paints and as a wood preservative is used with green "treated" wood containing high concentrations of Cu and As. Ingestion of either of these sources produces severe gastrointestinal upset with severe irritation of the epithelial layer of the gastrointestinal tract, hemolytic anemia, centrilobular hepatitis with jaundice, and renal damage. Excess Cu ingestion interferes with absorption of zinc[148] and can lead to zinc deficiency, which is frequently characterized by slow healing. The classical presentation of Cu toxicosis is represented by the genetic disease of Cu accumulation known as Wilson's disease.[105] This disease is typified by hepatocellular damage (increased transferases) and/or changes in mood and behavior because of accumulation of Cu in central neurons. The genetic basis for this disease has been identified.[78A]

Iron

The homeostasis and analysis of iron (Fe) are reviewed in Chapters 30. Iron supplements are used frequently to maintain an adequate body burden of Fe. Occasionally, ingestion exceeds the needed daily requirement, resulting in Fe toxicity.[23,43] Acute ingestion of more than 0.5 g of Fe can produce severe irritation of the epithelial lining of the gastrointestinal tract and result in hemosiderosis, which may develop into hepatic cirrhosis. The presence of excessive amounts of Fe in serum *and* urine defines this diagnosis. Although yet to be proven, chronic iron overload is thought to be linked to cancer[87] and atherosclerosis.[184]

Lead

Lead (Pb) is a metal commonly found in the environment. It can be an acute and chronic toxin.[103] Lead is present at high concentration (up to 35% w/w) in many paints manufactured before 1970. The Pb content of paints intended for household use was limited to <0.5% in 1972, but Pb is still found in paint products intended for nondomestic use and in artists' pigments. Ceramic products for use in homes, such as dishes or bowls, available from noncommercial suppliers (such as local artists) can contain significant amounts of Pb, which can be leached from the ceramic by weak acids, such as vinegar and fruit juices. Leaded crystal contains up to 10% Pb, which can be leached during long-term storage of acidic fluids, such as fruit juice. Lead is also found in dirt from areas adjacent to homes painted with Pb-based paints and on highways where it has accumulated from the use of leaded gasoline in automobiles. Use of leaded gasoline has diminished significantly since the introduction of unleaded gasoline, which has been required in personal automobiles in the United States since 1978. Lead is also found in soil near abandoned industrial sites where Pb may have been used. Water transported through Pb or Pb-soldered pipe contains some Pb, with higher concentrations found in water that is weakly acidic. Some foods (e.g., moonshine distilled in Pb pipes) and some traditional home medicines also contain Pb.[34] Exposure to Pb from any of these sources by ingestion, inhalation, or dermal contact can cause significant toxicity.

A typical diet in the United States contributes approximately 300 μg of Pb per day, of which 1% to 10% is absorbed; children may absorb as much as 50% of the dietary intake. The fraction of Pb absorbed is enhanced by nutritional deficiency. The majority of the daily intake is excreted in the stool after direct passage through the gastrointestinal tract. Although a significant fraction of the absorbed Pb is rapidly incorporated into bone and erythrocytes, Pb is ultimately distributed among all tissues. Lipid-dense tissues, such as the central nervous system, are particularly sensitive to organic forms of Pb. All Pb absorbed is ultimately excreted in bile or urine. Soft-tissue turnover of Pb occurs within approximately 120 days.[17]

Lead expresses its toxicity by several mechanisms that are described graphically in Figure 35-4. It avidly inhibits amino levulinic acid dehydratase (ALAD), one of the enzymes that catalyze synthesis of heme from porphyrin. Inhibition of ALAD causes accumulation of protoporphyrin in erythrocytes (see Chapter 32), which is a significant marker for Pb exposure. Anemia caused by the lack of heme is frequently observed in Pb toxicity. Lead also is an electrophile that avidly forms covalent bonds with the sulfhydryl group of cysteine in proteins. Thus proteins in all tissue exposed to Pb will have Pb bound to them. Keratin in hair contains a high fraction of cysteine relative to other amino acids and avidly binds Pb; hair analysis for Pb is a good marker for exposure. Some proteins become labile as Pb binds with them because Pb causes the tertiary structure of the protein to change; cells of the nervous system are particularly susceptible to this effect. Some Pb-bound proteins change their tertiary configuration sufficiently so that they become antigenic; renal tubular cells are particularly susceptible to this effect because they are exposed to relatively high Pb concentrations during clearance.

The development of Pb toxicity follows a progressive pattern. Figure 35-5 describes this progression through a series of symptoms.[146] The finding that Pb contributes significantly to decreased intellectual capability in the very

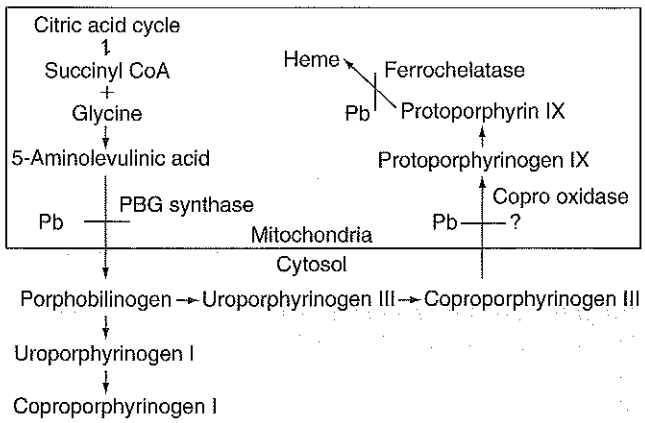

Figure 35-4 Erythropoietic effects of lead.

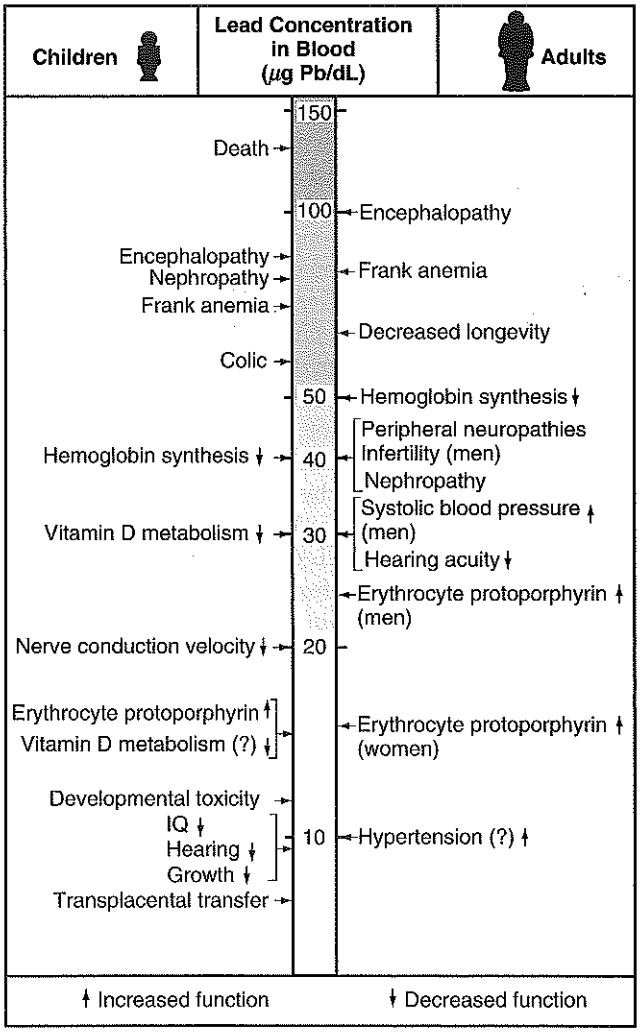

Figure 35-5 Effects of inorganic lead on children and adults (lowest observable adverse effect concentrations). *(From Royce SE, Needleman HL, Eds. Case studies in environmental medicine: Lead toxicity. Washington DC: US Public Health Service, ATSDR, 1990.)*

young is of particular concern.[132] Young children are particularly prone to the effects of Pb because they have greater opportunity for exposure.[8] Children tend to spend a lot of time on the floor. In older homes that have been previously treated with Pb-based paints, Pb-laden paint chips and dust accumulate on the floor, which children are likely to ingest.

The definitive test for Pb toxicity is measurement of blood Pb.[143] Over the past 3 decades, studies have shown an inverse relationship between blood Pb concentrations and children's IQ at increasingly lower Pb concentrations. In response, the CDC has continued to lower the upper limit of normal for children, which is now stated at less than 10 μg/dL. It is also important to note that the median blood Pb concentration is children fell from 15 μg/dL in 1978 to 2 μg/dL in 1999 because of measures such as the removal of Pb from gasoline.[140] Consequently, renewed interest in determining safe blood Pb concentrations resulted in additional studies.[139] These studies assessed the intellectual impairment in children with Pb concentration below 10 μg/dL. Preliminary data have indicated that there is an inverse relationship between Pb concentrations and children's IQ even at blood Pb concentrations below 10 μg/dL.[31] If additional studies show similar findings, it may be appropriate to review the current reference interval for blood Pb concentrations in children.

The WHO has defined whole blood Pb concentrations greater than 30 μg/dL in adults as indicative of significant exposure. Lead concentrations greater than 60 μg/dL require chelation therapy. Similar to the situation seen in children, adult blood Pb concentrations have dropped to a mean value of 1.4 μg/dL for ages 20 to 49 and a mean value of 1.9 μg/dL for ages 50 to 69.[125] Given the decreasing blood Pb concentrations in adults, it may be important to revisit the recommendations regarding Pb exposure. Studies have shown a number of adverse health effects in adults exposed to Pb at concentrations below existing regulatory exposure limits. These include hypertension, adverse reproductive outcomes, and subtle central nervous system problems.[21,153,168] In 2000 the CDC recommended that, as a preventive health measure, blood Pb concentrations in exposed workers be reduced to <25 μg/dL by the year 2010.[171]

Erythrocyte protoporphyrin concentrations are not a sensitive indicator of low-concentration Pb exposure[101] but are definitive markers for Pb overdose; an erythrocyte protoporphyrin concentration greater than 60 μg/dL is a significant indicator of Pb exposure (see Chapter 32). Serum ALAD concentrations are also a useful indicator for medium to high concentrations of Pb exposure; however, they do not correlate with low concentrations of Pb exposure.[35] Serum Pb analysis is of very limited utility, because Pb concentrations are abnormal only for a short period of time after exposure.[35] Normally the hair Pb content is lower than 5 ug/g; hair Pb concentration greater than 25 μg/g indicates severe Pb exposure. Quantification of urine excretion rates either before[11] or after chelation therapy[180] has been used as an indicator of Pb exposure. However, blood Pb levels have the strongest correlation with toxicity.

Avoidance of continued exposure to Pb is paramount when blood Pb concentrations exceed acceptable limits. Severe Pb toxicity may require chelation therapy using BAL, administered intravenously. Oral dimercaprol has become a standard therapy and is being used in the outpatient setting for all except those with the most severe Pb poisoning.[74] Although chelation therapy is effective in reducing blood Pb concentrations, a 2003 study indicated that chelation therapy given to preschool children with Pb concentrations in the range of 20 to 44 μg/dL showed no beneficial effect on tests of cognition or behavior.[140] Likewise, there are no placebo-controlled, randomized studies that demonstrate a positive impact on therapeutic outcome from chelation therapy in adults, only improvement in symptoms and decreased mortality.[98] Therefore, prevention may be the only real solution.

Analysis of Pb is routinely performed by either ICP-MS[26,124] or electrothermal atomic absorption spectrometry. EDTA anticoagulated blood is the specimen of choice for Pb analysis, because Pb is concentrated in the erythrocytes. Sodium heparin may also be used; however, samples that are not analyzed within 48 hours are frequently clotted and must be rejected. Care must be taken when obtaining capillary blood. Surface contamination, insufficient collection volume, and inadequate mixing with EDTA result in frequent sample rejection. Urinalysis can also be performed; urine quantification correlates with exposure.

If ICP-MS is used to measure Pb levels,[26,124] care must be taken to sum the masses of 206, 207, and 208 m/z to account for the natural isotopic variation of Pb in the environment. Failure to sum masses can skew results above or below the actual concentration, as the isotopic abundance of a particular mass in the calibrator might not match the sample. However, this isotopic variation can be exploited to determine the source of Pb exposure. By determining the relative abundances of Pb in blood and also of potential sources of exposure (e.g., paint chips and soil), a matching pattern can be identified. The exposure source with the same ratio of major Pb isotopes as the blood should then be avoided or removed from the patient's environment.

An ICP-MS method for quantifying Pb in whole blood is included in the appendix for this chapter that is found on the book's accompanying Evolve site (http://evolve.elsevier.com/Tietz/textbook/).

Manganese

Manganese (Mn) is ubiquitous in the environment. Specifically, manganese is (1) a binding agent in red brick, (2) present in most steel alloys as an anticorrosive, (3) used extensively in laboratories as a cleaning agent for glassware, and (4) a common pigment in paints and glazes. Humans exhibit toxicity to Mn when exposed to large quantities of dust containing the metal, which can occur in mining, ore crushing, the machining of Mn alloys, and the construction and destruction of brick. After chronic exposure, Mn accumulates in the substantia nigra of the brain, causing a Parkinson-like neurodegenerative disorder known as manganism.[28,52,112] Manganese toxicity has also been observed in children receiving long-term parenteral nutrition.[62]

Blood or urine Mn concentrations are good indicators of exposure.[104] Adult reference values for blood Mn are 0.4 to 1.1 ng/mL (7.0 to 20.0 nmol/L) for serum or plasma and 7.7 to 12.1 ng/mL (140 to 220 nmol/L) for whole blood. Typical daily excretion of Mn in urine is from 0.2 to 0.5 µg/day. However, approximately 5% of normal people excrete up to 2 µg of the metal per day, probably because of greater than average exposure.

Most of the Mn in daily diets is not absorbed. Because Mn-containing dust is common, contamination of urine with the metal can easily occur. Trace contamination of acid preservatives used for stabilizing the urine has also been observed. Manganese is quantified by electrothermal atomization atomic absorption spectrometry[122] or by ICP-MS.[26]

Mercury

Annually, the atmosphere and surface of the earth are exposed to approximately 36,000 tons of mercury (Hg), a product of the natural outgassing of rock (30,000 tons/yr), from industry used in electrolysis, in electrical switches, and as a fungicide (6000 tons/yr); and incorporated into dental amalgams (90 tons/yr).[161]

There is considerable opportunity for Hg exposure in our environment. Mercury is used as a conductor in many electrical switches; most home thermostats contain elemental Hg in a glass bulb to serve as a temperature switch. Mercury is used extensively in the pulp and paper industry as a whitener; the effluents from paper plants are a known source of Hg. Mercury is commonly used in industry as a catalyst in the synthesis of plastics and is frequently found in antifouling and latex paints because it is a potent fungicide. Mercury is approximately 50% of the mass of dental amalgams.[137] The single largest source of Hg in the environment is natural outgassing from granite rock; this source accounts for approximately 80% of all Hg accumulation in the environment.

Mercury is essentially nontoxic in its elemental form (Hg^0). In the absence of any chemical or biological system that chemically alters Hg^0, it can be consumed orally without any significant side effects. However, once Hg^0 is chemically modified to the ionized, inorganic species, Hg^{2+}, it becomes toxic. Further bioconversion to an alkyl Hg, such as methyl Hg (CH_3Hg^+), yields a very toxic species of Hg that is highly selective for lipid-rich tissue, such as the neuron.[42] The relative order of toxicity is as follows:

$$Hg^0(\text{Nontoxic}) < Hg^{2+} << CH_3Hg^+(\text{Very toxic})$$

Mercury can be chemically converted from the elemental state to the ionized state; in industry, this is frequently accomplished by exposing Hg^0 to a strong oxidant, such as chlorine. Elemental Hg can also be bioconverted to both Hg^{2+} and alkyl Hg by microorganisms that exist both in the normal human gut and in the bottom sediment of lakes and rivers. When Hg^0 enters bottom sediment, it is absorbed by bacteria, fungi, and related microorganisms; these organisms metabolically convert it to Hg^{2+}, CH_3Hg^+, $(CH_3)_2Hg$, and similar species. Consequently the methyl mercurials are accumulated in the aquatic food chain and reach their highest levels in predatory fish.[33,39]

As a consequence of methylmercury accumulating in the aquatic food chain, most human exposure to mercury happens through the eating of contaminated fish, shellfish, and sea mammals.[33,167] In adults, cases of methylmercury poisoning are characterized by the focal degeneration of neurons in regions of the brain such as the cerebral cortex and cerebellum. Depending on the degree of in utero exposure, methylmercury may result in effects ranging from fetal death to subtle neurodevelopmental delays. Consequently,

because pregnant women, women of childbearing age, and young children are particularly at risk, the U.S. Food and Drug Administration recommends that they avoid eating shark, swordfish, mackerel, and tilefish.[60] However, no definitive consensus has been reached to date on the safety level of maternal exposure during pregnancy.

Mercury toxicity is expressed in three ways. First, Hg^{2+} avidly reacts with sulfhydryl groups of protein, causing a change in the tertiary structure of the protein with subsequent loss of the biological activity associated with that protein; because Hg^{2+} becomes concentrated in the kidney during the regular clearance processes, this is the target organ that experiences the greatest toxicity. Secondly, with the tertiary change noted previously, some proteins become immunogenic, eliciting a proliferation of B-lymphocytes that generate immunoglobulins to bind the new antigen (collagen tissue are particularly sensitive to this). Thirdly, alkyl Hg species, such as methylmercury, are particularly lipophilic and avidly bind to proteins in lipid-rich tissue, such as neurons; myelin is particularly susceptible to disruption by this mechanism.[38,185] Mercury has also been found to alter porphyrin excretion patterns.[181]

Experience with Hg poisoning has been gained from investigation of the 1951 to 1963 industrial dumping of Hg-laden waste sludge into Minamata Bay, Japan. Fish in Minamata Bay became heavily laden with Hg through the food chain. The local human population whose diet was dependent on fish from the bay exhibited symptoms of methylmerecury poisoning, which include ataxia, impaired speech, visual field constriction, hearing loss, and somatosensory change, characterized histologically by cerebral cortex necrosis.[170] Collectively, these symptoms have become known as Minamata disease.[59]

In the late 1980s, the public became concerned about exposure to Hg from dental amalgams.[76,137] However, later studies have failed to confirm a causal relationship.[6,78,172] Basic to the initial concerns was the fact that restorative dentistry used a Hg-silver amalgam for approximately 90 years as a filling material. In 1989 Hahn showed that there is a small (2 to 20 μg/day) release of Hg^0 from amalgam when it is mechanically manipulated, such as by chewing.[76] The normal bacterial flora present in the mouth convert a fraction of Hg^{2+} to CH_3Hg^+; the latter has been shown to be incorporated into body tissue. In addition, the habit of gum chewing can cause release of Hg from dental amalgams at concentrations greatly above normal. Hanson noted in 1991 the release of up to 100 μg/day of Hg in several human subjects who had the typical placement of dental amalgams (weighing approximately 800 mg each) after chewing gum for 8 hours.[77]

Concerns have also been raised about the possible relationship between Hg exposure from vaccines and autistic disorders. In the United States, the prevalence of autism has risen from 1 in approximately 2500 in the mid 1980s to 1 in approximately 300 children in the mid1990s.[70] Several investigators believe that this rise is because of the Hg that is present in vaccines as the preservative thimerosal (sodium ethyl mercury thiosulfate).[12-14,46,70,71] However, this causality has been questioned by numerous other studies who have not been able to confirm this relationship.* In 2001 the Committee on Immunization Safety Review of the Board on Health Promotion and Disease Prevention of the Institute of Medicine (IOM) initiated a study to review the connection between Hg-containing vaccines and neurodevelopmental disorders, including autism. The committee has issued several reports and in their eighth and final one in 2004, they reported that the hypothesis was biologically plausible, but that there was insufficient evidence to accept or reject a causal connection and recommended a comprehensive research program.[88] The findings of this report have been challenged,[14] and it has even been recommended that thimerosal be removed from all vaccines in the United States.[71] Some Scandinavian countries have already removed it from their vaccines.[94,160]

Dietary sources can also contribute to Hg body burden, as many foods contain Hg. For example, commercially distributed fish considered safe for consumption contain less than 0.3 μg/g, but some game fish contain more than 2 μg/g and if consumed on a regular basis, contribute to significant body Hg loads.

Analysis of blood, urine, and hair for Hg levels is used to determine exposure. The quantity of Hg found in blood and urine correlates with degree of toxicity, and hair analysis is used historically to document the time of peak exposure. However, it should be noted that hair analysis for metals in general is difficult because of contamination. Normal whole blood Hg concentration is usually lower than 10 μg/L. Figure 35-6 shows a distribution of blood concentrations seen in a large population composed of unaffected, healthy individuals.[124] Individuals who have mild occupational exposure (e.g., dentists) may routinely have whole blood Hg concentrations of up to 15 μg/L.[56] Significant exposure is indicated when the whole blood Hg concentration is greater than 50 μg/L (if exposure is to methylmercury) or greater than 200 μg/L (if exposure is to Hg^{2+}). The WHO safety standard for daily exposure of Hg is 45 μg per day, with a daily urine excretion exceeding 50 μg/day indicating significant exposure. Normally, hair contains less than 1 μg/g of Hg; greater amounts indicate increased exposure. Treatment with BAL or penicillamine will mobilize Hg, allowing for its excretion in the urine. Therapy is usually monitored by following urinary excretion of Hg; therapy may be terminated after the daily urine excretion rate falls below 50 μg/L.

An ICP-MS method for quantifying Hg in biological specimens is included in the appendix for this chapter that is found on this book's accompanying Evolve site http://evolve.elsevier.com/Tietz/textbook/).

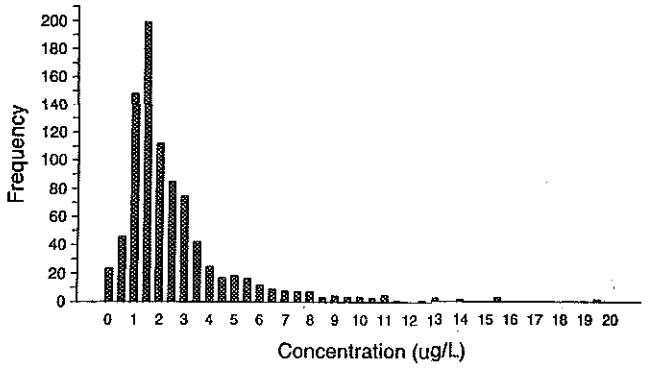

Figure 35-6 Distribution of blood mercury in a healthy population.

Nickel

Nickel (Ni) is frequently used in the production of metal alloys (which are popular for their anticorrosive and hardness properties), in Ni-based rechargeable batteries, and as a catalyst in the hydrogenation of oils. Elemental Ni is nontoxic except that it will induce inflammation at point of contact.[134] It is likely that Ni is essential for life at very low concentrations. Nickel carbonyl ($Ni[CO]_4$), used in petroleum refining, is one of the most toxic chemicals known to humans.[155] Nickel carbonyl is absorbed after inhalation, readily crosses all biological membranes, and noncompetitively inhibits ATPase and RNA polymerase.* Patients exposed to Ni carbonyl exhibit rapid onset of pulmonary congestion and inability to oxygenate hemoglobin, followed by development of lesions of the lung, liver, kidney, adrenal glands, and spleen.[91,106] Other compounds of Ni have been found to be toxic in the rat.[133]

Patients undergoing dialysis are exposed to Ni and accumulate Ni in blood and other organs. There appear to be no adverse health effects from this exposure.[123] Nickel is quantified by electrothermal atomic absorption spectrometry.[123]

Platinum

A variety of platinum (Pt)-containing antineoplastic agents are used in chemotherapy, typified by cisplatin (*cis*-dichlorodiammineplatinum dihydrate).[29,55] All of these compounds have some nephrotoxicity that is related to the concentration of Pt circulating in the blood.[48] Although it is not common to measure Pt concentrations in all patients receiving cisplatin therapy, quantification of Pt concentrations in patients with reduced renal function can help identify whether the Pt is the cause of the compromised renal function. Peak serum concentrations greater than 1 μg/mL but less than 1.5 μg/mL correlate with little nephrotoxicity and good therapeutic response.[67] Either AA-ETA or ICP-MS can be used to measure Pt.[4]

Selenium

Selenium (Se) is an essential element and may play a role in mitigating biological damage caused by arsenic and cadmium exposure.[128] It is a cofactor required to maintain glutathione peroxidase activity, an enzyme that catalyzes the degradation of organic hydroperoxides. The absence of Se correlates with a loss of glutathione peroxidase activity and is associated with damage to cell membranes because of the accumulation of free radicals. In humans, cardiac muscle is the tissue most susceptible to Se deficiency; with cell membrane damage, normal cells are replaced with fibroblasts.[64] This condition is known as *cardiomyopathy* and is characterized by an enlarged heart consisting of predominantly nonfunctioning fibrotic tissue.

The normal daily dietary intake of Se is 0.01 to 0.04 ppm, which is similar to the typical content of the metal in soil (0.05 ppm) and sea water (0.09 ppm). Excessive exposure occurs when daily intake exceeds 0.4 ppm.[183] Selenium accumulates in biological tissue such that the normal concentration in human blood serum is 95 to 160 ng/mL (0.15 ppm). In the state of Se deficiency associated with loss of glutathione peroxidase activity, the serum concentration is less than 40 ng/mL.[136]

Selenium deficiency among people who consume food from only a particular region can be related to low soil content of the metal in that region; the soil of the Keshan region of China is noted for this characteristic. Children living in the Keshan region who receive no Se supplement develop cardiomyopathy. Deficiency is also related to use of total parenteral nutrition, which is therapy administered to patients who have no functional bowel (e.g., those who have undergone surgical removal of the small and large intestines because of cancer) or who have acute inflammatory bowel disease, such as Crohn's disease (see Chapter 48). Selenium supplementation to raise serum concentration above 90 ng/mL is the usual practice in these patients, and serum monitoring on a semiannual basis is performed to ensure adequacy of supplementation.

Selenium toxicity has been observed in animals when daily intake exceeds 0.44 ppm.[183] Teratogenic effects are frequently noted in the offspring of animals living in regions where Se soil content is high, such as in south central South Dakota and the northern coastal regions of California.[159] Selenium toxicity in humans is not known to be a significant problem except in acute overdose cases, and Se is not classified as a human teratogen. Selenium is found in many over-the-counter vitamin preparations because its antioxidant activity is thought to be anticarcinogenic.[175] There is no substantiating evidence that Se inhibits cancer development.[159]

Selenium may be quantified by ICP-MS,[26] or alternatively by atomic absorption spectrometry, after the specimen is

*Of historical note, an epidemic occurred in 1976 in Philadelphia that became known as "legionnaires' disease." Before the cause was identified as microbiological, serious consideration was given to the possibility that the cause was nickel carbonyl, because the presentation of the patients resembled that expected for those exposed to this toxic metal complex.

mixed with matrix modifier. An ICP-MS procedure for measuring selenium in serum is presented in the appendix for Chapter 35 found on this book's accompanying Evolve site at http://evolve.elsevier.com/Tietz/textbook/.

SILICON

Silicon (Si) is the most abundant element in our environment; it constitutes 26% of the earth's crust. From the toxicological viewpoint, several forms of Si are of interest, including amorphous oxides of Si (e.g., asbestos) and methylated polymers of Si (e.g., silicone).

Inhalation of asbestos-containing dust leads to deposition of asbestos fibers in the pulmonary alveoli.[120] These fibers are needle-shaped spicules approximately 150 μm in length and up to 15 μm in diameter. When these fibers are inhaled, they deposit in the alveoli where they are surrounded by macrophages and become coated with protein and mucopolysaccharide to form "asbestos bodies." The diagnosis of asbestosis is made by interpretation of a chest x-ray by a qualified radiologist, demonstration of asbestos in sputum, and documentation of asbestos bodies in a lung biopsy by electron microscopy.[69,141] Direct analysis of lung tissue for Si is not useful, because all lung tissue is infiltrated with Si, most of which is not asbestos. Thus direct analysis for Si cannot distinguish asbestosis from normal background Si.

Concern about the use of silicone in implants and about its possible toxicity have come to public attention based on reports of a high prevalence of connective tissue disease associated with breast augmentation.[19,45] Silicone appears to induce a response from polymorphonuclear cells and macrophages that bind small particles of silicone and transport them to lymph nodes, where they can accumulate.[156] Other studies do not support a rheumatological role for silicone.[65,147,179] Quantification of blood[131] or tissue concentrations[111] correlates with the presence of implants but not with symptoms of joint disease.

SILVER

The clinical interest in silver (Ag) analysis is limited to two applications: (1) monitoring burn patients treated with Ag sulfadiazine and (2) monitoring patients treated with Ag-containing nasal decongestants. In both cases, Ag deposits in many organs, including the subepithelium of skin and mucous membranes, producing a syndrome called *argyria* (graying of the skin). Argyria is associated with growth retardation, hemopoiesis, cardiac enlargement, degeneration of the liver, and destruction of renal tubules. The normal concentration of serum Ag is less than 2 ng/mL. Typical Ag concentrations observed in serum of unaffected patients during treatment range up to 300 ng/mL, and their urine output can be as high as 550 μg/day.[177]

THALLIUM

Thallium (Tl) is a byproduct of lead smelting. Interest in Tl derives primarily from its use as a rodenticide; accidental exposure represents the most likely source of exposure. Additionally, environmental concerns are growing because thallium is a waste product of coal combustion and the manufacturing of cement.[84] Thallium is rapidly absorbed via ingestion, inhalation, and skin contact. It is considered to be as toxic as lead and mercury and has similar sites of action.[84,109,164] The mechanism of Tl toxicity is (1) competition with potassium at cell receptors to affect ion pumps, (2) inhibition of DNA synthesis, (3) binding to sulfhydryl groups on proteins in neural axons, and (4) concentration in renal tubular cells to cause necrosis. Patients exposed to high doses of Tl (>1 g) demonstrate alopecia (hair loss), peripheral neuropathy and seizures, and renal failure.[69] Normal serum concentrations are less than 10 ng/mL, and normal daily urine excretion is less than 10 μg/day. Exposed patients can have serum concentrations as high as 50 μg/mL, with urine output in excess of 500 μg/day. The long-term prognosis from such an exposure is poor.[36]

Principles of Molecular Biology and Approaches to Nucleic Acid Isolation

*Y.M. Dennis Lo, M.A., D.M., D.Phil., F.R.C.P., F.R.C.Path., and Rossa W.K. Chiu, M.B.B.S., Ph.D., F.R.C.P.A.**

Molecular diagnostics represents one of the most rapidly developing areas in clinical chemistry. Advances in the field have been made possible by our improved understanding of molecular biology and genetics and of their relationships with human diseases, and the development of powerful technologies for the analysis of nucleic acids. The chapters in this section attempt to provide an overview of the important advances in molecular diagnostics. The fundamental concepts in molecular biology are reviewed in this chapter. Molecular diagnostic techniques and operational requirements are discussed in Chapters 37 and 38, respectively. The subsequent chapters focus on key areas of molecular diagnostics, specifically hematological malignancies (Chapter 39), inherited diseases (Chapter 40), identity assessment (Chapter 41), infectious diseases (Chapter 42), and pharmacogenetics (Chapter 43).

LANDMARK DEVELOPMENTS IN GENETICS AND MOLECULAR DIAGNOSTICS

Amazing developments in biotechnology have taken place in the late twentieth century.[38] For example, we have witnessed the decoding of the human genome, cloning of organisms, and progress in stem cell research and gene therapy. Many of these advances would not have been possible without the many earlier landmark discoveries that unveiled the mysteries of genetics and paved the way for modern molecular diagnostics.[2,31] Genetics began modestly when Mendel experimented with garden peas. His findings, published in 1866 and suggesting the concepts of alleles and genes as discrete units of heredity, essentially captured the most fundamental concepts in inheritance. In 1910 Morgan revealed that the units of heredity are contained within chromosomes, but it was Avery in 1944 who confirmed through studies on bacteria that it was DNA that carried the genetic information. Franklin and Wilkins studied DNA by x-ray crystallography, which subsequently led to the unraveling of the double-helical structure of DNA by Watson and Crick in 1953. In the 1960s Smith demonstrated that DNA can be cleaved by restriction enzymes, which Arber had discovered earlier and which facilitated the subsequent development of recombinant DNA technologies. Nathans furthered the work on restriction enzymes and was the first to construct a genetic map. In 1975 the Southern blot was invented, which allowed the detection of specific DNA sequences. Soon after, in 1977, DNA-sequencing methodologies were developed, and the first complete DNA sequence of an organism, a bacteriophage, was published. Prenatal genetic diagnosis of sickle cell disease was first shown to be feasible by Kan and Chang in 1981. Mullis and co-workers developed the polymerase chain reaction (PCR) in 1985. DNA microarrays, which allow the simultaneous interrogation of gene transcripts, became a reality in 1996. Remarkably, the draft human genome sequence was released in 2001 and completed in 2003.

*The authors gratefully acknowledge the original contributions of Drs. Elizabeth R. Unger and Margaret A. Piper, upon which portions of this chapter are based.

This is a brief account of a fraction of the many great discoveries that shaped modern genetics and molecular diagnostics. We shall now start the discussion of the principles of molecular biology beginning with the Watson and Crick model of DNA and, for the readers who persist in the journey, the chapter shall end with discussion of the greatest biotechnological achievement of mankind of our time, the Human Genome Project.

NUCLEIC ACID CHEMISTRY, BIOCHEMISTRY, AND BIOLOGY

Nucleic acids form the repository for hereditary information and provide the means of translating that information into the cellular machinery of life. Detailing the structure and function of nucleic acids has been a central theme of molecular biology; a review of nucleic acid chemistry and biochemistry is fundamental to further discussions on nucleic acid diagnostic tests.

Molecular Compositions and Structures of DNA and RNA

The physicochemical properties and function of nucleic acids are largely governed by the compositions and structures of DNA and RNA. A single molecule of DNA is a polymer consisting of a backbone of invariant composition and of side groups arranged in a variable sequence. The polymer is synthesized from monomers (nucleotides) composed of the sugar deoxyribose, a phosphate residue, and a purine or pyrimidine base. The purines are *adenine* (A) and *guanine* (G), and the pyrimidines are *cytosine* (C) and *thymine* (T) (Figure 36-1). The four nucleotide building blocks of DNA are abbreviated dATP (deoxyadenine-triphosphate), dGTP (deoxyguanine-triphosphate), dCTP (deoxycytosine-triphosphate), and dTTP (deoxythymine-triphosphate), respectively. Nucleotides are joined by phosphodiester bonds that link the 5′-phosphate group of one to the 3′-hydroxyl group of the next (Figure 36-2). There are no 3′-3′ or 5′-5′ linkages; thus the sugar and phosphate moieties compose the nonspecific portions of the molecule. The sequence of the bases varies from molecule to molecule and uniquely identifies each DNA polymer, which as discussed later, determines the identity and function of the protein or RNA products that the DNA encodes.

Although the purines and pyrimidines are of different compositions and sizes, when in the proper orientation, adenine forms hydrogen bonds with thymine and guanine forms hydrogen bonds with cytosine to form planar structures of similar dimensions (Figure 36-1). This and the fact that the base portion of each nucleotide is hydrophobic contributes to the energetically favorable secondary structure of DNA as it is found in its native form: a right-handed, double-stranded helix. The planar *base pairs* stack in the inside of the helix, 10 bases per turn, whereas the hydrophilic sugar-phosphate backbone forms noncovalent bonds with surrounding water molecules. For the two DNA polymers to form the proper hydrogen bonds between the bases, two requirements must be fulfilled: the polymers must run in opposite directions *(antiparallel)* as defined by the free hydroxyl groups at each end (3′-5′ vs. 5′-3′), and the sequences of each molecule must be such that A:T and G:C hydrogen bonds are always formed *(base pairing)*. Two DNA strands that meet this requirement are called *complementary*.

Owing to base pairing and the double-helical conformation, double-stranded DNA (dsDNA) is an exceptionally stable molecule. Retention of the base pairs in the inner portion of the helix prevents disruption by water molecules. The helical conformation places each monomer in an identical orientation within the molecule and forms the same secondary bonds as every other monomer. This secondary bonding contributes to the overall stability. Because the base

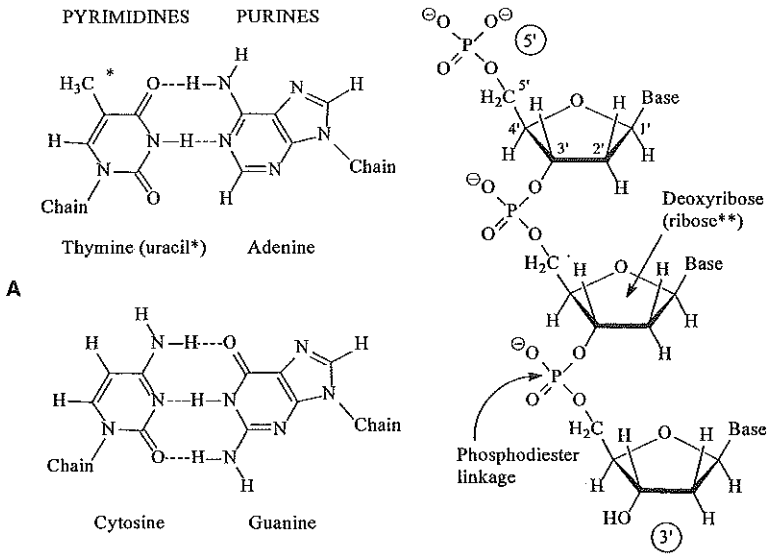

Figure 36-1 Purine and pyrimidine bases and the formation of complementary base pairs. *Dashed lines* indicate the formation of hydrogen bonds. (In RNA, thymine is replaced by uracil, which differs from thymine only in its lack of the methyl group.) *(Modified from Piper, M.A., Unger, E.R.: Nucleic Acid Probes: A Primer for Pathologists. Chicago, ASCP Press, 1989.)*

pairs are of similar size, the helix retains a constant angle of rotation and avoids distortion. All of these features dictate that all dsDNA molecules, regardless of base sequence, retain the same shape and size within a pH range of approximately 4 to 9. Outside these limits, the base pair bonds are disrupted and the helix unwinds.[90]

RNA is chemically very similar to DNA but differs in important ways. The sugar unit is ribose with an added hydroxyl group at the 2′ position, and the methylated pyrimidine *uracil* (U) replaces thymine. RNA exists in various functional forms but typically as a single-stranded polymer that is much shorter than DNA and that has an irregular three-dimensional structure. Research from recent years has revealed that RNA conformations are not random structures and the folding mechanism of RNA molecules is complex.[19,99] The secondary structure adopted by an RNA molecule is to a large extent related to its nucleotide sequence. The secondary structure for particular RNA sequences can be as regular as the secondary structure of a protein. It is now known that RNA molecules can further interact to form complex tertiary structures, which are intimately related to novel functions of RNA, such as the catalytic activity of ribozymes.[19,99]

Chromosome Structure

DNA molecules are extremely long and in the eukaryotic cell are maintained in orderly and compact three-dimensional structures. Each diploid human cell contains two full complements of the human genome, each copy consisting of approximately 3.2 billion nucleotides. This vast amount of genetic material is organized into 23 homologous chromosome pairs, with each pair contributed by a homolog of maternal origin and the other of paternal origin. Each chromosome is a highly-ordered structure of a single dsDNA molecule, compacted many times with the aid of structural DNA-binding proteins. The chromosomal arrangement of human DNA not only allows the packaging of the vast human genome into the limited physical dimensions of the cell nucleus, but also governs one of the Mendelian laws of inheritance on independent assortment whereby genes located on different chromosomes recombine at random from one generation to the next. In addition, as will be discussed later, the structural organization of the human genome is intimately related to the control of DNA transcription, replication, recombination, and repair.[2,37,46]

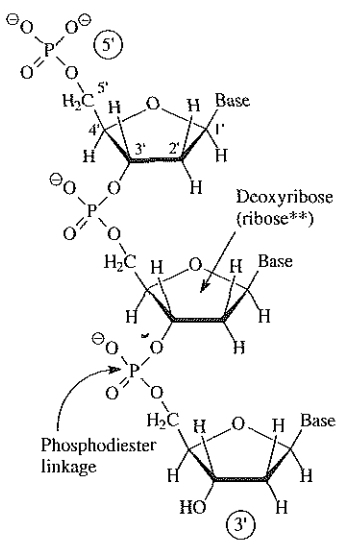

Figure 36-2 A single-stranded DNA chain. Repeating nucleotide units are linked by phosphodiester bonds that join the 5′ carbon of one sugar to the 3′ carbon of the next. (In RNA, the sugar is ribose, which adds a 2′-hydroxyl to deoxyribose.) *(Modified from Piper, M.A., Unger, E.R.: Nucleic Acid Probes: A Primer for Pathologists. Chicago, ASCP Press, 1989.)*

Nuclear DNA in conjunction with its associated structural proteins, including histone and nonhistone proteins, is known as *chromatin*. Chromatin is arranged and organized in a hierarchical fashion where the degree of condensation increases with higher levels of structural organization. The *nucleosome* represents the most basic level of chromatin organization and is present as repeated units along the full length of each chromosome. Each nucleosome unit consists of a nucleosome core particle and 20 to 80 base pairs of linker DNA, which spans between adjacent nucleosomes.[70] A nucleosome core particle involves 146 base pairs of dsDNA tightly wound around an octamer of histone proteins, two each of four histone proteins, namely H2A, H2B, H3, and H4.[71] The linker DNA segments are associated with the linker histone H1. Nucleosomes are further packed in successive levels of complexity wherein the most compact stage,[37] chromatin, appears as discrete mitotic chromosomes as seen in the metaphase of a cell cycle. Integrity of the nucleosomal structure is crucial to the maintenance of the higher-order arrangements of chromatin.[70]

Chromatin condensation is a dynamic process that changes in a coordinated fashion in association with the cell cycle. In general, chromatin is much less condensed during interphase, at which time DNA is replicated. However, the extent of chromatin condensation during interphase varies among regions of the genome. Genomic regions that are rich in genes are in general less compactly organized and are termed *euchromatin*. Regions that are gene-poor or span over transcriptionally silent genes are more densely packed and are called *heterochromatin*. Our understanding of the biological role of heterochromatin and the mechanisms that govern its formation and assembly has improved in recent years. Heterochromatin is important for the maintenance of specialized chromatin structures, X-chromosome inactivation in females, maintenance of genome stability by stabilizing repetitive DNA sequences, and regulation of gene expression.[33] Eukaryote chromosomes contain two specialized regions of heterochromatin, namely the centromeres and telomeres. The former plays an important role in directing the movement of chromosomes between daughter cells during cell division, while the latter contains repetitive nucleotide sequences that are located on and protect the ends of chromosomes. Besides the large centromeric or

telomeric blocks of heterochromatin, smaller domains of heterochromatin are scattered throughout the genome and are associated with the control of gene expression. The assembly of heterochromatin starts at the most basic level of chromatin organization, the nucleosomes, and involves DNA methylation, histone modifications, noncoding RNAs, and sequence-specific DNA binding proteins.[33] The functional implications of the structural organization of chromatin will be discussed further below.

Replication, Transcription, and Translation

Each time a cell divides, the entire DNA content of that cell must be faithfully duplicated, so that the total complement of hereditary information (the *genome* of the organism) is retained in each daughter cell. This process is called *replication*. Owing to the laws of base pairing (i.e., adenine pairs only with thymine, and guanine only with cytosine), the sequence of a single strand of DNA dictates the sequence of its complementary strand. Replication proceeds in a *semiconservative* fashion, with the two parent strands of a dsDNA molecule each serving as the template for the synthesis of a daughter strand. The duplicated dsDNA molecules produced in this manner are each composed of one parent strand and one daughter strand. For replication to occur, the original double-stranded helix must be separated, which is an energetically unfavorable event. This is accomplished with a combination of DNA-specific proteins and enzymes, and synthesis of both daughter strands proceeds as the parent strands separate. Replication is initiated at multiple sites during this process, but each origin of replication is used only once during a single cell cycle.

Daughter strands are synthesized by *DNA polymerase III,* an enzyme that reads the parent template and attaches nucleotides to the growing daughter strand according to the base-pairing rules of dsDNA. DNA polymerase III begins synthesis at the replication fork, the point of strand separation, with a short RNA primer that base-pairs to the parent template. Later, this primer is excised and replaced with DNA by the DNA repair enzyme, *DNA polymerase I.* Because DNA polymerase III synthesizes DNA only in the 5′-3′ direction, one daughter strand is synthesized continuously, whereas the other must be synthesized discontinuously. The fragments on the discontinuous strand are then joined by the *DNA ligase* enzyme. Many other proteins are involved in unwinding and stabilizing the parent strands for synthesis, in protecting single-stranded regions, in recognizing initiation sites, and in synthesizing the RNA primer. In addition to synthetic capabilities, the DNA polymerases possess an exonuclease or "proofreading" function: When an incorrect nucleotide is added to the growing polymer, a conformational change brings the chain in contact with the exonuclease portion of the enzyme, which excises the incorrect nucleotide. This helps maintain the integrity of the original DNA sequence.

The information in DNA is arranged in units specifying production of proteins and RNA molecules required for cellular function. These units, called *genes,* include coding regions specifying the amino acid sequence of a protein and the regulatory regions controlling the rate and timing of that protein's production. The production of proteins is mediated by RNA molecules that carry the information for specific proteins from the DNA in the nucleus to the cytoplasm, where the proteins are synthesized. These are *messenger RNAs* (mRNAs). The process of transferring the sequence information from the coding regions of DNA to the RNA message is called *transcription.*

Like replication, transcription requires separation of the duplex DNA strands and uses a polymerase to copy the template DNA strand. For transcription, the polymerase is *RNA polymerase II,* which binds to sequences in the regulatory region of the gene called the *promoter.* Promoters occur approximately 100 bases "upstream" (i.e., at the 5′ end) from the initiation site of transcription where the first ribonucleotide unit is paired with the template (uracil pairs with adenine). Promoters are usually rich in thymine and adenine in repeating patterns and have been referred to as a *TATA box.* Initiation of transcription requires many protein cofactors to bind to RNA polymerase to form the active initiation complex. Other regions of DNA known as *enhancers* may interact with the initiation complex to stimulate or repress transcription. Regulation of transcription is the primary mechanism cells use to control gene expression.[88]

Transcription continues until chain termination occurs in response to specific sequences. The RNA transcript quickly detaches from the template DNA because restoration of the DNA-DNA duplex is energetically more favorable than retaining the DNA-RNA hybrid or a segment of ssDNA. The end product is a complementary sequence of ribonucleotides that contains the information necessary for protein synthesis. However, additional modifications are required before mRNA can be exported to the cytoplasm where protein synthesis takes place.[2] The 5′ end is modified by the addition of 7-methyl guanosine residues to form a structure called a *cap.* The 3′ end is modified by the addition of multiple adenine bases, called the *poly A tail.* Both caps and tails are necessary for translation of mRNA into protein, and the poly-A tail may also stabilize the mRNA molecule. Noncoding regions termed *introns* are excised from the mRNA by a molecular complex termed a *spliceosome.* These complexes are composed of multiple small nuclear ribonucleoprotein particles (snRNPs). Spliceosomes mediate the cleavage and ligation of RNA at specific recognition sequences. After the introns are removed, the mRNA contains *exons,* or coding sequences, and is transported into the cytoplasm.

Translation is the process whereby the mRNA sequence directs the amino acid sequence during protein synthesis. Twenty-one amino acids are involved in protein synthesis and each is specified by a three-nucleotide sequence known as a *codon.* Because there are 64 possible codons, most amino acids are specified by more than one codon. In addition, two codons do not code for amino acids but always signal termination of protein synthesis (stop codons), and one codon,

TABLE 36-1 The Genetic Code (Translation of mRNA to Amino Acids During Protein Synthesis)

		Nucleotide Position in the Codon			
1st	**2nd**	**3rd**

*The codon UGA can code for either selenocysteine or stop.

UGA, codes for either a stop or for selenocysteine, depending on the adjacent sequences or RNA-binding proteins.[36] The genetic code is shown in Table 36-1. Translation takes place on *ribosomes*, which are ribonucleoprotein complexes that function as protein synthesis factories. A ribosome binds to the initiation site on mRNA to form an initiation complex. During synthesis, codons are "read" by *transfer RNA* (tRNA), short RNA molecules that have a sequence complementary to an amino acid codon *(anticodon)*, and are bound to the amino acid molecule specified by the codon. As synthesis proceeds, the appropriate tRNA anticodon base-pairs with the next mRNA codon. An enzyme on the ribosome then catalyzes the formation of a peptide bond between the amino acid bound to the tRNA and the growing protein chain. The previous tRNA is released and the next tRNA is added. The ribosome moves along the mRNA until a stop codon is reached and synthesis is complete. The ribosome and the protein product are then dissociated from the mRNA. More than one ribosome can move along an mRNA molecule at a time, forming a *polyribosome.*

Genetics and Epigenetics

Genetic and epigenetic phenomena are intimately related. In general, genetic events are related to the sequence information of DNA, and thus include the consequences of the transmission of a particular DNA sequence (e.g., the inheritance of DNA mutations or polymorphisms) or the acquisition of DNA sequence variations (e.g., the accumulation of somatic mutations in aging or cancer development). These genetic issues are discussed in some of the subsequent chapters. On the other hand, there have been inconsistent views regarding the definition of epigenetics.[34] In most circumstances, epigenetics encompasses processes that alter gene function or its interpretation by mechanisms other than those that rely on DNA sequence change.[39] Practically, epigenetics has evolved to include the study of DNA methylation, genomic imprinting, histone modification, chromatin remodeling, and others.[75] Most of these processes add another dimension to gene expression control.

DNA methylation refers to the addition of a methyl group to the fifth carbon position of cytosine residues in CpG dinucleotides. Approximately 80% of all CpG dinucleotides in the human genome are methylated and these mainly include isolated CpG dinucleotides and clusters, termed CpG islands, in nonpromoter DNA repeat elements.[75] These patterns of methylation are faithfully reproduced during DNA replication by maintenance DNA methyltransferases (DNMT1), so that the methylation pattern is inherited by daughter cells at cell division. In addition, DNA methylation is implicated in growth and development of organisms. After embryo fertilization, the genome becomes demethylated (except imprinted loci, see discussion later in this chapter) to pave the way for the establishment of developmentally related patterns of DNA methylation by de novo DNA methyltransferases (DNMT3a and DNMT3b). Genomic imprinting and gene dosage compensation of X-linked genes in females are also mediated by DNA methylation. Genomic imprinting is an epigenetic phenomenon whereby the genetic function of particular alleles is determined by whether it is paternally or maternally inherited. The human insulin-like growth factor-2 H19 *(IGF2-H19)* locus on chromosome 15 is an example of an imprinted locus whereby the

disomic inheritance of either the paternal or maternal allele results in significantly different clinical outcomes, namely Prader-Willi and Angelman syndromes, respectively (see Chapter 40, Inherited Diseases). Differential methylation of the imprinted locus from the time of germ cell development allows the recognition of the parental origin of the imprinted alleles by the cellular processes.

Besides growth and development, DNA methylation is a well-recognized epigenetic phenomenon that mediates gene silencing.[43] With the exception of CpG islands within DNA repeat elements, other CpG islands, particularly those found in promoter regions of active genes, are unmethylated in the homeostatic state. If, on the contrary, the promoter CpG islands become hypermethylated, the genes would become transcriptionally silenced. Aberrant hypermethylation of gene promoters, particularly those of tumor suppressor genes and genes involved in DNA repair, is a well-known phenomenon in tumor development.[42] The methylation of gene promoters has been shown to hinder the association of methylation-sensitive transcription factors, thus preventing gene activation. In addition, hypermethylated sites attract the binding of methyl-CpG binding proteins, such as methyl-CpG binding protein 2 (MECP2) and methyl-CpG binding domain proteins (MBD1 and MBD2), which further block the association of a number of transcription factors.[42] More importantly, it is now appreciated that these methyl-CpG binding proteins have the ability to recruit histone deacetylases, a phenomenon that leads to deacetylation of histones and that ultimately represses transcription.

As discussed, histones are an integral part of nucleosomes, the basic repeating structural unit of chromatin. The amino termini of histone proteins can be modified post-translationally by processes that include acetylation, methylation, phosphorylation, and ubiquination.[45] Acetylation of the lysines on the amino termini of histones H3 and H4 by histone acetyltransferases decreases histone-DNA interaction and improves the accessibility of DNA to transcriptional activation. On the contrary, histone deacetylation by histone deacetylases promotes the formation of compact nucleosomes, leading to repression of transcription. Histone deacetylation is in fact a key component to the assembly of heterochromatin, the transcriptionally inactive chromatin.[33] Methylation of the ninth amino acid residue, lysine, on histone H3 generates a binding site for heterochromatin protein (HP1) and thus is another key event in heterochromatin formation.[103] Phosphorylation of the tenth amino acid, serine, on histone H3 is important for chromosome condensation and mitosis.

Besides the histone modifications, nucleosomes can be remodeled by ATP-dependent processes, including octamer sliding, DNA looping, and histone substitution.[46] Octamer sliding allows the relocation of histone octamers to adjacent DNA segments. DNA looping refers to the mechanism whereby the DNA segment originally wrapped around the nucleosome could be unlooped. Histone substitution allows the replacement of octamer subunits with variant histones. Consequently, nucleosomes are dynamic structures that can be remodeled according to the transcriptional demands of the cell. Furthermore, energy-dependent processes also exist that facilitate the remodeling of higher-order chromatin structures with implications on genetic events, such as DNA transcription, replication, repair, and recombination.[75] In summary, gene function is moderated by an interrelated web of epigenetic mechanisms. The interdependency between the control of gene function or expression and the structural organization of chromatin can be appreciated from the dual structural and functional effects of CpG methylation, histone modification, heterochromatin formation, and nucleosomal and chromatin remodeling.

Nuclear and Mitochondrial Genomes

Up to this point we have focused our attention on the nuclear genome only. Yet, in fact, it is not the only genome in the cell, the mitochondrial genome being the other important genetic component of eukaryotic cells. The human mitochondrial genome is a circular piece of DNA 16.5 kb in length.[107] Mitochondrial DNA is transmitted between generations by maternal inheritance, with the mitochondria coming from the oocytes and not (usually) from sperm. Multiple copies of mitochondrial DNA are present within each mitochondrion and each cell contains a variable number of mitochondria depending on the energy requirements of the particular cell type. Thus certain cell types may contain up to several thousand copies of mitochondrial DNA.[87,93] This greater abundance, compared with that of nuclear DNA, makes mitochondrial DNA attractive for tests for which sample DNA is limited (e.g., crime scenes, pathogen detection, and paleontology). Mitochondrial DNA is double-stranded for most of its length except at the replication and transcription control region (the D-loop). Unlike the nuclear genome, the mitochondrial genome is not packaged into nucleosomal units. Instead, it has a unique structural organization, which researchers have just begun to unravel.[1,4] It encodes for 13 polypeptides, all involved in the oxidative phosphorylation pathway; two ribosomal RNAs (rRNAs); and all of the 22 tRNAs required for mitochondrial protein synthesis. Several other proteins are also required for normal mitochondrial function and are encoded by nuclear genes.

The mutation rate of mitochondrial DNA is 10 to 20 times higher than that of nuclear DNA. This high rate has been viewed as a result of the poor fidelity of mitochondrial DNA polymerase.[41,55] Germ-line mutations in the mitochondrial genome generally lead to neurodegenerative and/or myopathic diseases, such as MELAS (myopathy, encephalopathy, lactic acidosis, and strokelike episodes) and Leber's hereditary optic neuropathy.[55] Somatic mutations, on the other hand, are associated with aging and cancer development.[108] Consequent to the accumulation of sequence variations, more than one population of mitochondrial DNA sequences may be present in a cell. This state is termed *heteroplasmy* as opposed to homoplasmy in which the cell

contains a homogeneous population of mitochondrial genomes. When performing genetic analysis for mitochondrial DNA, a note of caution is warranted on the potential problems related to the presence of nuclear pseudogenes, which are DNA segments in the nuclear genome with significant homology to the mitochondrial genome.[110] The close resemblance of the nuclear and mitochondrial DNA segments may result in the false-positive detection of mitochondrial DNA sequences[109] and thus the specificity of PCR systems for mitochondrial DNA detection needs to be carefully evaluated.[82] Disorders associated with mitochondrial DNA and tests for the disorders are discussed in Chapter 40.

Circulating Nucleic Acids

Apart from studies in the field of virology, most molecular analyses have been performed on DNA and RNA that have been extracted from cells. In the 1940s, however, intriguing data appeared that pointed toward the existence of cell-free DNA and RNA in the plasma of human subjects.[73] However, apart from a handful of reports,[52-54] the field of circulating nucleic acids remained largely dormant until the 1990s. Since that time, interest in cell-free DNA has grown rapidly, largely because of its potential to provide new tools in molecular diagnostics.

Cancer DNA in Plasma

In 1994 two groups simultaneously reported the presence of tumor-associated oncogene mutations in DNA in the plasma and serum of cancer patients.[96,105] These reports were rapidly followed by the detection of other cancer-associated molecular changes in DNA found in plasma and serum, including microsatellite alterations,[10,76] oncogene amplifications,[11] epigenetic changes,[24,111,112] mitochondrial mutations,[80] and viral nucleic acids.[64,74] The detection and quantification of circulating tumor-derived DNA in plasma and serum have been shown to allow the detection,[64] monitoring,[58,66,100] and prognostication of a variety of cancers.[6,44,63]

The mechanism through which DNA is released into the plasma and serum has generally been thought to be because of cell death,[40] probably through a combination of apoptosis and necrosis. Consistent with this view, circulating DNA in cancer patients has been shown to consist mainly of short DNA fragments.[7,32] The functional implication of circulating tumor DNA remains unclear, although provocative hypotheses have been proposed regarding the possibility that such DNA may mediate "genometastasis."[29,30]

Fetal DNA in Maternal Plasma

The presence of tumor-derived DNA in the plasma of cancer patients has inspired researchers to look for other types of circulating nucleic acids. In particular, the similarity between the placenta and a malignant neoplasm[97] has led to the discovery of cell-free fetal DNA in the plasma and serum of pregnant women.[65] Fetal DNA has been shown to be present in the plasma of almost all pregnant women, from the early first trimester onward,[21] and to be present in increasing concentrations as gestation progresses.[67] Following delivery, fetal DNA is cleared rapidly from maternal plasma, with an apparent half-life on the order of 16 minutes.[69]

The discovery of cell-free fetal DNA in maternal plasma and serum has opened up new possibilities for noninvasive prenatal diagnosis. Fetal DNA is readily detectable in maternal plasma, but most of the DNA in maternal plasma is still of maternal origin.[67] Thus most workers in the field have attempted to detect unique genetic markers that the fetus has inherited from the father (e.g., Y chromosomal markers for a male fetus). This technology has now been used for the noninvasive prenatal diagnosis of a number of conditions, including sex-linked disorders,[21] RhD status,[59] congenital adrenal hyperplasia,[12] achondroplasia,[89] and β-thalassemia.[13] Fetal RhD status determination in RhD-negative women has been adopted as a routine service by several laboratories.[26] In addition to the qualitative mutation analyses of fetal DNA in maternal plasma, quantitative aberrations have also been reported in a number of pregnancy-associated disorders, including preeclampsia,[61,115] preterm labor,[56] trisomy 21,[51,60] hyperemesis gravidarum,[92] and invasive placentation.[91] These data have generally been produced by the measurement of fetal-derived Y chromosomal DNA sequences in the plasma or serum of women carrying male fetuses. Thus if a gender- and polymorphism-independent fetal-specific marker could be developed in the future, fetal DNA measurement might be used as an additional analyte for prenatal screening.

Other Applications of Circulating DNA

Apart from oncology and fetomaternal medicine, plasma DNA also has other applications in molecular diagnostics. In a situation analogous to the presence of a fetus in a preg-nant woman, DNA derived from a transplanted organ has also been detected in the plasma of the transplant recipient.[68,72] It has been hypothesized that a measurement of graft-derived DNA concentration might provide a noninvasive method for monitoring graft rejection, analogous to the situation of urine DNA measurement following kidney transplantation.[113,114] In addition, the association between plasma DNA and cell death[27,28] has also prompted investigators to measure circulating DNA concentration in various conditions associated with tissue injury, including pulmonary embolism,[104] trauma,[48,62,85] myocardial infarction,[8] and stroke.[86]

Plasma RNA

The detection of cell-free DNA in plasma has prompted investigators to see if cell-free RNA may also be present in the plasma. This was first achieved through the detection of tumor-derived RNA, including tumor-associated viral RNA[57] and a tissue-specific mRNA transcript,[47] in the plasma and serum of cancer patients. Since then a number of RNA targets, including telomerase components[9,23] and multiple epithelial mRNA transcripts,[94] have been detected in the plasma and serum of patients suffering from a variety of cancers.

One apparent paradox in the detection of RNA in plasma is the well-known lability of RNA. Indeed, if purified RNA is added to plasma, the RNA molecules are largely degraded within a matter of seconds.[101] However, when endogenous plasma RNA is studied, the RNA molecules have been shown to be remarkably stable, with concentrations remaining unchanged for extended periods at room temperature.[101] The stability of endogenous plasma RNA has recently been shown to be related to the fact that such RNA molecules appear to be associated with particulate matter.[78] One possible nature of such particulate matter is apoptotic bodies.[35]

Fetal RNA has been found in the plasma of pregnant women.[83] Recently, the placenta has been shown to be a major organ responsible for the release of fetal RNA into maternal plasma.[79] Thus placental mRNA transcripts, such as human placental lactogen,[79] the beta-subunit of human chorionic gonadotropin,[79] and corticotrophin releasing hormone,[77] have been detected in maternal plasma. Through the use of expression microarray analysis, literally hundreds of new fetal RNA markers potentially suitable for maternal plasma detection could be developed.[102] The quantitative analysis of placental mRNA in maternal plasma has the potential to be used in the monitoring of pregnancy-associated disorders such as preeclampsia.[25,77]

Apart from cancer and pregnancy, circulating RNA has also been detected in patients with acute trauma.[84] It is expected that further clinical applications will be forthcoming during the next few years.

NUCLEIC ACID ISOLATION

Many of the key advances in understanding of DNA and RNA have been achieved by study of purified nucleic acids. In the molecular diagnostic laboratory, some tests can be performed directly on samples of biological fluids, but techniques for isolation of nucleic acids often are critical.

DNA Isolation

Extraction of DNA and/or RNA is a key preliminary step to subsequent molecular analysis. Quite a number of protocols have been developed over the years. In selecting the most appropriate protocol for one's laboratory, some of the issues worth considering include the specimen type and volume required, yield, purity, size of the isolated nucleic acids, ease of operation, throughput, cost, and whether the protocol involves the use of hazardous reagents or is amenable to automation. With the advent of PCR, molecular analyses could be performed on a variety of specimens, including whole blood, plasma, serum, tissue biopsies, cultured cells, buccal swabs, cerebrospinal fluids, amniotic fluids, paraffin-embedded tissue, and so on. Although there are a variety of commercial protocols available for DNA extraction, most protocols can be classified into a few categories that involve either liquid- or solid-phase extraction. In general, solid-phase extraction methods are more commonly used because of the relative ease of operation, the ability to process large batches of specimens, high reproducibility, and adaptability to automation. However, solution-based methods are still favored when large quantities of DNA or large sample volumes are involved.

Because the phosphate esters of the nucleic acid backbone are strong acids and exist as anions at neutral pH, DNA is soluble in water up to about 1% of weight of solute per volume of solution and can be precipitated by the addition of alcohol. Alcohol precipitation has therefore been used in many nucleic acid extraction protocols. In general, most DNA extraction protocols involve an initial step of cell lysis whereby both the cellular and nuclear membrane envelopes are disrupted. Cellular proteins are then removed by salt precipitation or degraded enzymatically. An additional step of RNase digestion is optional. The genomic DNA that remains in solution is then precipitated by the addition of alcohol. The DNA precipitate is isolated and rehydrated. The resultant DNA extract can be stored until subsequent analysis. For the solution-based protocols, cellular and protein debris is usually separated from the soluble DNA fraction by solvent extraction through the use of solvents with different solubility constants. The well-known phenol-chloroform protocols are based on this principle. After the DNA is precipitated by alcohol, the DNA pellet is isolated by manual removal of the excess alcohol solution. Careful attention to this step is required to prevent the inadvertent removal of the DNA pellet, which can be quite fine or loose in some instances. Before rehydration of the DNA pellet, it is air-dried to remove the remaining drops of alcohol. Because of the number of manual steps involved, the sample throughput of these solution-based methods is limited.

On the other hand, solid-phase extraction methods are more robust. These methods involve the use of either silica membranes or magnetic particles. Both methods take advantage of the reversible binding of DNA with the respective solid phases. Silica can bind nucleic acids in a reversible manner dependent on the ionic strength of the environment.[95] Silica-based methods usually involve the impregnation of silica onto a filter, which is housed in a plastic column. After cell lysis and protein digestion, DNA is precipitated by the addition of alcohol. The solution is then allowed to pass through the silica-impregnated filter, which binds and purifies the DNA from other debris present in the alcohol solution. Either centrifugation or vacuum manifolds can be used for the filtration step. The bound DNA is usually washed and subsequently eluted using nuclease-free water or low ionic strength buffers. Similarly, methods based on the use of magnetic particles allow the isolation and purification of alcohol-precipitated DNA from other debris by placing the solution under a magnetic field whereby DNA molecules precoated with magnetic beads are retained. The magnetic beads are subsequently removed from the purified DNA before the final elution step. Both the silica-based and magnetic particle–based methods are applicable to various scales of operation. Isolated columns can be used for the extraction

of a small number of specimens. The 96-well plate formats are available from some commercial providers, and allow the processing of specimens at medium throughput. Moreover, the protocols can be further adapted for use on automated platforms for large-scale processing.[22,50]

RNA Isolation

RNA analysis and therefore RNA extraction are required for studies on gene expression. RNA molecules are generally less stable than DNA because unlike DNA, RNA is not protected by a stable double-helical conformation and in addition, RNA is subject to alkaline hydrolysis via its 2′-hydroxyl group of the ribose moiety. Although both DNA and RNA can be degraded enzymatically by DNA- and RNA-specific nucleases (DNase and RNase, respectively), RNases are nearly ubiquitous, making it much more difficult to work with native RNA molecules in the laboratory. Thus certain issues warrant special attention when one works with RNA, including its extraction.[20] Because of the inherent instability of RNA, clinical specimens intended for RNA analysis should either be processed promptly in the fresh state; preserved by the immediate addition of preservation agents, such as RNA*later*™ (Ambion®, Austin, TX); or snap-frozen by liquid nitrogen. The number of freeze-thaw cycles should be minimized and this is equally applicable to solutions of extracted RNA. Utmost care is needed to prevent RNase contamination and this includes the use of RNase-free reagents, RNase-free plastic ware, and the cleaning or decontamination of the working surfaces and equipment with RNase-free detergents or chemicals. Water treated with diethylpyrocarbonate (DEPC) for the inactivation of RNase should be used. As the DNA sequence of eukaryotic genes differs from their mRNA counterparts only by the presence of introns, there exists a possibility in which both DNA and RNA segments are co-amplified in specimens contaminated with DNA. Therefore care must be taken to avoid DNA contamination. Alternatively, DNA digestion by DNase I treatment is commonly incorporated as an additional step during the process of RNA purification.

The underlying principles for RNA extraction are essentially identical to those of DNA isolation and purification. Both solution-based and solid-phase extraction protocols are available. Similarly, RNA molecules are first released by lysis of cells; isolated and purified from the protein and lipid debris, either by phenol-chloroform extraction or reversible binding to silica; and precipitated by use of alcohol. However, the composition of lysis buffers typically includes phenol (e.g., Trizol, Invitrogen, Carlsbad, Calif.), sodium dodecyl sulfate, or guanidinium salts, as these buffers not only lyse cells directly, but also inhibit RNase effectively.[14] The successful isolation of high quality RNA is thus dependent to some extent on the degree of cellular exposure to these denaturants. Therefore tissue specimens need to be ground to a fine powder form before lysis. To prevent RNA degradation during grinding, the procedure should be performed on either snap-frozen tissue or specimens preserved with RNA stabilizing agents.[20] The above procedures are relevant to the isolation of total RNA, which comprises mRNAs, rRNAs, small nuclear RNAs, and tRNAs. However, protocols have been developed for the isolation of mRNA, which are based on the capture of the polyadenylated tails on the 3′ ends of mRNA by hybridization to cellulose-bound oligo(dT) molecules.[20]

Assessment of Nucleic Acid Yield and Quality

Nucleic acid molecules absorb ultraviolet light maximally at 260 nm owing almost entirely to the constituent bases. Thus DNA or RNA yield can be quantified by spectrophotometric measurement of the absorbance at 260 nm. Alternatively, isolated nucleic acids can be subjected to agarose gel electrophoresis and their yield quantified by densitometric measurements.

Both spectrophotometric and densitometric methods can be used for the assessment of the quality of the extraction of DNA and RNA. Purity can be evaluated by assessing the ratio of the absorbances at 260 nm and 280 nm (A_{260}/A_{280}), the latter reflecting the presence of the aromatic amino acids in contaminating protein. Values greater than 1.8 indicate minimal contamination with protein. The sizes of the isolated genomic DNA can be estimated by gel electrophoresis. Total RNA integrity can be assessed by estimating the size distribution of the extracted RNA and the appearances of the 18S and 28S rRNA peaks. With RNase degradation, the RNA size distribution will be shifted toward the smaller fragments and the rRNA peaks would become less discernible. Similarly, high quality mRNA preparations isolated by oligo(dT)-cellulose should display broad size ranges.

In assessing the yield and quality of DNA/RNA extracts, electrophoretic methods provide better precision and more information regarding quality, for instance the size distribution of the isolated DNA/RNA. Yet, these methods generally require significantly higher amounts of the extracted sample when compared with spectrophotometric assessment. However, automated analyzers that use prefabricated chips with microfluidic channels and are designed for the electrophoresis of microvolumes of DNA and RNA have become available.[81] These instruments allow the sensitive and precise quantification and qualitative assessment of nucleic acids.

Techniques for analysis of nucleic acids are described in the next chapter.

THE HUMAN GENOME PROJECT

The Human Genome Project is the biggest biological project ever undertaken by mankind. Apart from its ambitious goal of deciphering the 3 billion base pairs that make up the human genetic code, it also represents a model for the planning, organization, and execution of large-scale biological projects.[16,17] The first serious discussion of the feasibility of such a project can be traced back to the mid 1980s. In 1988 a special committee of the U.S. National Research Council of the U.S. National Academy of Sciences formulated a 15-

year human genome project, costing some $200 million a year. A genetic map with 1 cM resolution was accomplished in September 1994. A physical map involving 52,000 sequence-tagged sites (STSs) was completed in October 1998. The final journey to the completion of this project was marked by a highly publicized race between a publicly funded group of investigators and a private effort. The public effort, undertaken by the International Human Genome Sequencing Consortium, consisted of investigators from 20 centers located in six countries: the United States, the United Kingdom, Japan, China, France, and Germany. The completion of a draft sequence was announced June 26, 2000, and it was published in two landmark papers, one from the public team and one from the private team, in February 2001.[49,106] The final sequence was accomplished in April 2003, with 99.99% sequencing accuracy, with no gaps.

The human genome consists of 3.2 Gb of DNA. Among these sequences, some 2.95 Gb consists of weakly staining, potentially gene-rich euchromatic regions. Only some 1.1% to 1.4% is sequence that encodes proteins. Over half of the DNA consists of various types of repeated sequences. The number of genes in the human genome has been estimated to be between 26,000 and 31,000. These estimates provide an interesting comparison with the 6000 genes estimated for a yeast cell, 13,000 for a fruit fly, 18,000 for a worm, and 26,000 for a plant.[3] With the basic sequence decoded, the project that awaits biologists would be the even more difficult task of elucidating the biological functions of these stretches of DNA.

An understanding of our genetic heritage has the potential of providing a quantum leap in our understanding of the biology of life. It would also greatly enhance our ability to elucidate the molecular basis of diseases. For example, through the data generated from the Human Genome Project, new disease-associated genes are being discovered almost every week, as compared with the early multiyear efforts that resulted in the identification of the genes responsible for each single-gene disorder, such as cystic fibrosis.[45] Developments in the genome project have also given us enhanced ability to develop tests for the molecular diagnosis of numerous diseases. In the longer term, these developments also provide new targets for the pharmaceutical industry.

Apart from its scientific merits, it is important to realize the enormous nonscientific implications of the Human Genome Project. It was visionary for the early proponents of the Human Genome Project to set aside part of the budget of the project to study the social, legal, and ethical implications of this project.[15] The most commonly expressed fear by the public is that genetic information may be used in ways that could harm people, such as barring them from getting insurance, employment, or other social opportunities. Important steps have been taken by legislators to safeguard against genetic discrimination, such as the passing of the Genetic Information Nondiscrimination Act by the U.S. Senate in 2003.[18]

The Human Genome Project can be regarded as a foundation on which future large-scale biological projects can be built.[17] One important extension of our knowledge of the human genome is a detailed understanding of the heritable variation in the human genome. One class of such variations is the single nucleotide polymorphisms (SNPs). A public project, the International HapMap Project, has been launched to study the patterns of linkage disequilibrium and haplotypes across the human genome and to characterize SNPs.[98] Another large-scale project is the Encyclopedia of DNA Elements (ENCODE) Project (http://www.genome.gov/ENCODE/), which aims to identify all of the functional elements in the human genome. A feasibility study involving 1% of the human genome has been done. Our understanding of life is likely to be expanded in a synergistic manner by related efforts, such as the Human Epigenome Project,[5] which aims to elucidate all of the methylation sites in the 30,000 human genes in approximately 200 samples, and the rapidly growing field of proteomics. The twenty-first century will likely be the century when a key biological revolution will take place.

CHAPTER 37

Nucleic Acid Techniques*

Carl T. Wittwer, M.D., Ph.D.,
and Noriko Kusukawa, Ph.D.

The tools of molecular diagnostics allow analysis of medically important sequence variations despite an always-present background of complex genomic structure. We begin this chapter by considering the organization of human, bacterial, and viral genomes, and the spectrum of variations in nucleic acids that are of medical concern. We will then describe the enzymes that allow us to process nucleic acids into forms that are amenable to analytical interrogation. We then discuss amplification techniques that are often necessary to allow observation of the alterations of interest or to quantify a specific nucleic acid sequence in a sample. Then the tools used to detect or visualize nucleic acids are discussed. Finally specific methodologies are described that allow identification, quantification, and/or segregation of individual nucleic acid species.

Developers of molecular diagnostic techniques are extremely competitive. Converts to one technique, instrument, or probe design often adopt a religious fervor and commitment. In this chapter, we have avoided cute trade names that, in our opinion, do not belong in the scientific literature. To misquote the Bard's fool, "... if you think our presentation less familiar, please accept that our intent was not to offend, perhaps inspection of the references will mend."

GENOMES AND NUCLEIC ACID ALTERATIONS

Before discussing nucleic acid alterations that are of medical interest, we review and expand on the description of the structure of genomes presented in Chapter 36. We emphasize concepts that are important when developing and using the techniques of molecular diagnostics.

Human Genome

As mentioned in the previous chapter, each human cell contains two copies of a 3.2-billion-member sequence code of nucleic acids on 46 chromosomes. Box 37-1 lists statistics for the human genome and the types of variation found in the genetic sequence that are important in clinical diagnostics.

Three quarters of human DNA is *intergenic* or between genes. More than 60% of this intergenic sequence consists of "parasitic" DNA regions of transposable elements 100 to 11,000 bases in length. Between 2 million and 3 million of these elements are present in each copy of the genome. They contribute to genetic recombination and chromosome structure, and provide an evolutionary record of mutation and selection.

Intergenic DNA also carries most of the simple sequence repeats (SSRs) present in the genome. These repeats are known as *microsatellites* or *short-tandem repeats* (STRs) when the repeat unit is 1 to 13 bases, and *minisatellites* or *variable number of tandem repeats* (VNTRs) when the repeat unit is 14 to 500 bases. SSRs are critical markers in genetic linkage studies, and in forensic or medical identity testing. They are formed by slippage during replication and are highly polymorphic between individuals. The most common SSRs are dinucleotide repeats such as ACACAC and ATAT. On average, approximately one SSR occurs every 2000 bases.

One quarter of the human genome consists of genes. There are about 30,000 genes in the human genome. The average gene covers 27,000 bases, but only about 1300 of these bases code for amino acid sequence. These coding regions, or exons, are interspersed throughout the gene. On average, there are about nine exons per gene. The noncoding areas between exons are known as *introns*. Within a gene, 95% of the sequence is covered by introns, while only 5%

*Parts of this chapter are based on the original contributions by Elizabeth R. Unger, Ph.D., M.D., and Margaret A. Piper, Ph.D., M.P.H.: Nucleic Acid Biochemistry and Diagnostic Applications (2nd and 3rd editions). These contributions are thankfully acknowledged.

BOX 37-1 The Human Genome and Its Sequence Variation

The Human Genome: 3.2 billion base pairs, 23 chromosome pairs (47-245 million base pairs per chromosome)

Genes (25%)		*Intergenic Sequences (75%)*	
24%	Intron sequences	45%	Parasitic (transposon-derived repeats)
1.1-1.4%	Exon sequences	5%	Segmental duplications
		3%	Simple sequence repeats (SSRs, STRs)
		22%	Other

Number of genes: ~30,000
Average gene:
- 27,000 base pairs
- 9 exons
- 1340 bases of coding sequence
- 446 amino acids

Sequence Alterations: 99.9% identity (1 difference every 1250 bases between randomly selected haploid genomes)

Single Nucleotide Polymorphisms (SNPs): identified every 100-300 bases
- 97% Noncoding
- 3% Within exons

Disease-Causing Mutations
- 70% SNPs
  - 49% Missense (amino acid substitution)
  - 11% Nonsense (termination)
  - 9% Splicing
  - <1% Regulatory
- 23% Small insertions/deletions
- 7% Gross lesions (large insertions/deletions, repeats, rearrangements, complex)

Epigenetic Alterations
Variable initiation
Alternative splicing
Methylation (regulation)
Histone phosphorylation, methylation, acetylation

Data compiled from the Human Gene Mutation Database[93] and Lander et al.[51]

consists of coding sequence within exons. Coding sequences comprise only 1.1% to 1.4% of the total genome.

Sequence Variation Within the Human Genome

If you compare the genome from any two individuals, you will find on average one difference every 1250 bases (i.e., approximately 99.9% of the sequence is identical between randomly chosen copies of the genome). The most common sequence variations are single base changes, also known as *single nucleotide polymorphisms* or SNPs. Millions of SNPs have been described, and many new SNPs continue to be reported. Some SNPs are common in the population with allele frequencies of 0.1 to 0.5 (i.e., present in 10 to 50 of every 100 copies studied), though others are very rare. Although an SNP has been identified every 100 to 300 bases, many of these are not found frequently in the population. The vast majority of SNPs (97%) occur in noncoding regions; only 3% of SNPs are associated with exons.

Sequence Variations That Cause Human Disease

Many of the sequence variations in the genome do not affect human health. For example, SNPs and SSRs found in the intergenic sequence are rarely associated with disease. Similarly, most of the SNPs in introns, except for splicing and regulatory mutations, are not known to affect gene function. In addition, some of the SNPs within exons are silent alterations that do not code for a change in amino acid sequence because of the redundancy in the genetic code. Still other SNPs in exons code for amino acid changes that do not affect protein function. Even such silent SNPs may nonetheless be of considerable medical interest as genetic markers. (See also Chapter 40, Inherited Diseases.)

Single Nucleotide Polymorphisms

Of the sequence alterations that are known to cause disease (and we will use the word *mutations* specifically for these types of alterations), about 70% are SNPs, followed in frequency by small insertions/deletions and gross lesions (see Box 37-1). Most of these SNPs are *missense* mutations and cause an amino acid substitution, while significantly fewer are *nonsense* mutations that change an amino acid code to a termination code resulting in premature polypeptide chain termination. Approximately 9% of disease-causing mutations are SNPs that alter the splicing sites located just outside of an exon, resulting in altered concatenation of coding sequences. Finally, less than 1% of known disease-causing mutations are SNPs that affect the regulatory efficiency of transcription by altering promoter/enhancer regions in introns or the stability of the RNA transcript.

Insertion, Deletions, Rearrangements, and Short-Tandem Repeats

The small insertion/deletion mutations account for about 23% of the nucleic acid sequence alterations that cause disease. An insertion refers to the presence of extra bases while deletion implies the absence of certain bases in comparison to a reference sequence. Insertion and deletion mutations often result in a shift of the codon reading frame, resulting in altered amino acid sequence downstream of the mutation—commonly followed by chain termination from a nonsense codon. *Indels* are deletions followed by insertions (e.g., replacement of AGGTC by TG).

The remaining mutations are mostly larger lesions and comprise only 7% of human mutations. These include whole gene duplications and deletions, SSR expansions (e.g., trinucleotide repeat expansions), gene rearrangements (e.g., B- and T-cell gene rearrangements), and complex polymorphic loci related to health and disease (e.g., HLA).

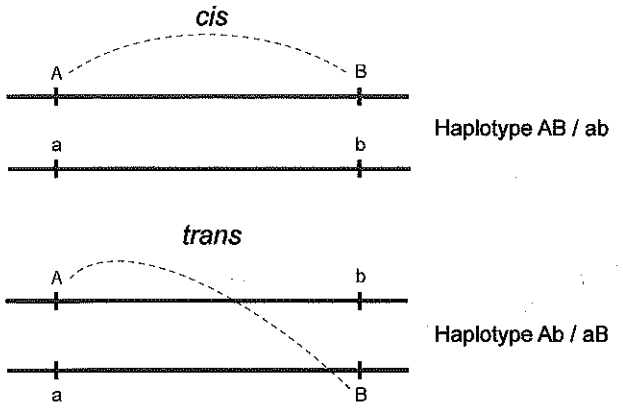

Figure 37-1 Schematic diagram of haplotypes. Two polymorphic sites reside on each of the two chromosomes of a chromosome pair. At a polymorphic site, one of two or more DNA sequences may be present. In the schematic, one site on each chromosome may have either the sequence (allele) designated as "A" or the sequence variation (allele) called "a." The other site may have either the sequence (allele) designated as "B" or the sequence variation called "b." The possible *haplotypes* are: AB/ab in which allele A and allele B are on the same chromosome (in which case A and B are said to be in *cis*), or Ab/aB in which allele A and B are on different chromosomes (and are referred to as being in *trans*).

Examples of mutations in human genes are discussed in more detail in Chapter 40, Inherited Diseases.

Haplotypes

Often, sequence variants are inherited together in a contiguous block, or *haplotype*. A schematic representation of haplotypes (and *alleles*) and an explanation are given in Figure 37-1 and its legend.

Disease associations may depend not on any particular mutation but on the overall effect of several linked alleles that define the haplotype. For example, enzyme function depends on the haplotype that defines the amino acid sequence in the protein. When the haplotype linkage of alleles is strong (e.g., in the example in Figure 37-1, when allele A is always found with allele B on the same chromosome) genotype determination at a single locus may identify the haplotype (and disease association) with high confidence. By contrast, methods for determining the *cis/trans* phase of alleles at distant loci are necessary when the haplotype linkage is weak and also when the disease association and/or haplotype linkage is first being established. Haplotypes may be defined by the phases of many polymorphic loci.

Alterations in Mitochondrial DNA

Most human genetic material is present in two copies, with the exception of the unpaired sex chromosome in males and mitochondrial DNA. The presence of only a single copy of genes on the X and Y chromosome in males leads to well-known sex-linked disorders. In contrast, the 16,500 bp mitochondrial genome is present in over 1000 copies per cell, constituting about 0.3% of human DNA. Allele fractions may vary over a wide range when all mitochondria in a cell are considered. That is, mutations in mitochondrial DNA are *heteroplasmic*, meaning the ratio of wild-type to mutant alleles within a cell can vary almost continuously, sometimes resulting in a wide range of symptoms even when only one mutation is involved. See Chapter 40 for discussion of disease associated with mutations in mitochondrial DNA.

Numerical Gene Alterations and Cellular DNA content

Sometimes genes or even chromosomes are present in more than two copies. If extra copies of genes lose their function, they are known as pseudogenes. It is important to distinguish pseudogenes from functional genes since sequence variations in pseudogenes are seldom of clinical importance. Some very important genes are present in many copies so that overall protein expression is not affected if a chance mutation occurs in one copy. Most genes, however, are present in two copies and the normal gene dosage is two. When these genes, such as *HER-2-neu*, are present in more than two functional copies, the genes are said to be *amplified*. As a result, more mRNA transcripts and protein are usually made, resulting in cellular abnormalities and possible progression to cancer. Many cancers and some genetic disorders are correlated with abnormal (increased or decreased) chromosome numbers or *aneuploidy*. The specific chromosomal alterations can be determined by cytogenetics, or the overall DNA content can be determined by flow cytometry.

Human Epigenetic Alterations

In addition to the sequence alterations considered above, epigenetic alterations, including alternative splicing and methylation, affect gene expression. (See the heading "Genetics and Epigenetics" in the preceding chapter for descriptions and discussion.) Even though the number of genes may be limited to 30,000, variable transcription initiation and exon splicing is estimated to produce about 90,000 mRNA transcripts and protein products.

Methylation of cytosine to form 5-methylcytosine occurs frequently; about 70% of CpG dinucleotides in the human genome are methylated. Although not inherited, interest in this "5th base" has increased recently as correlations with cancer have been reported.[50] CpG islands are about 1000 bases in length and are often found near the 5′-end of genes. These regions consist of clusters of CG dinucleotides that are usually not methylated in normal cells. However, CpG methylation correlates with condensed chromatin structure and promoter inactivation; an important example occurs in tumor-suppressor genes.

As described in the preceding chapter (Chapter 36), DNA is associated with proteins in nucleosomes.[42] Gene expression can be altered by histone phosphorylation, acetylation, and methylation. Our understanding of epigenetic alterations and their relation to disease is rapidly developing.

Bacterial Genomes and Sequence Alterations

Bacterial genomes are considerably less complex than human or other eukaryotic genomes. Common bacteria have only one chromosome, usually a circular DNA double helix of 4 million to 5 million base pairs, about 1000 times less than the amount of DNA in a human cell. About 90% of the DNA in bacteria codes for protein. There are no introns, but there are multiple small intergenic regions, dispersed throughout the genome, that carry repetitive sequences. The common bacterium *Escherichia coli* contains about 4300 genes.

In addition to the large circular chromosome that carries essential genes, bacteria also carry accessory genes in smaller circles of double-stranded DNA known as plasmids. Plasmids range in size from 1000 to over 1 million base pairs. Plasmids are important in molecular diagnostics as they often encode pathogenic factors and antibiotic resistance.

The bacterial repertoire of DNA can be altered by: (1) gain or loss of plasmids; (2) single-base changes, small insertions, and deletions as in eukaryotic genomes; and (3) larger segmental rearrangements, including inversions, deletions, and duplications. Some genes, such as those for ribosomal RNA, are present in many copies and can be used to identify different species of bacteria. In addition, the intergenic repetitive sequences can serve as multiple targets for oligonucleotide probes, enabling the generation of unique DNA profiles or fingerprints for individual bacterial strains.

Viral Genomes and Sequence Alterations

Viral genomes are considerably less complex than bacterial genomes. Common viruses that infect humans vary in size from about 5000 to 250,000 bases, or 20 to 1000 times less than the amount of nucleic acid in *E. coli*. Because viruses use the host's cellular machinery, they do not need as many genes. Small viruses may encode only several genes, but the larger viruses can encode hundreds. The viral genome consists of either DNA or RNA, and the nucleic acid may be single-stranded or double-stranded, linear, or circular with one or multiple fragments and/or copies per viral particle. As in bacteria, there are no introns. In fact in some viruses, the exons overlap with different reading frames coding different products from the same nucleic acid sequence. Noncoding regions are usually present at the terminal ends of linear genomes. Repeat segments are often found as terminal or internal repeats and may be inverted.

Sequence alterations in viruses are common. Areas of high sequence variation may be interspersed between conserved domains. Higher frequencies of variation can be correlated with lower polymerase fidelity and may allow escape from antibody recognition and from antiviral drugs. Common mutations in viruses include point mutations, insertions, and deletions. Sequence diversity within a viral species may be so great that consensus sequences for molecular typing are difficult to find.

NUCLEIC ACID ENZYMES

Nucleic acid enzymes are critical tools for the techniques used in molecular diagnostics. Common enzymes that act on nucleic acids include those that synthesize longer polymers and those that degrade nucleic acid into shorter fragments. These enzymes are critical for DNA replication and RNA transcription and must be present in all cells that replicate. In addition to general-function enzymes, a variety of unique enzymes, found in bacteria and viruses, act on specific nucleic acid sequences. Many of these enzymes have been purified and synthesized in vitro, sometimes "engineered" with alterations that improve their performance or stability (e.g., at high temperatures needed to dissociate double-stranded DNA in laboratory tests). Our ability to manipulate nucleic acids in vitro with these enzymes has made modern molecular biology possible. They are also used extensively in nucleic acid diagnostics, including sample preparation, probe labeling, signal generation, and amplification of targets and probes.

Nucleases are enzymes that hydrolyze one or more phosphodiester bonds in nucleic acid polymers. Nucleases may require a free hydroxyl end (exonucleases), with specificity for the 3′ or 5′ end, or may act only on internal bonds (endonucleases). For example, some probe techniques are based on 5′-exonuclease activity that cleaves nucleic acids between two fluorescent labels. Nucleases can be DNA- or RNA-specific and may act on only double- or single-stranded polymers. For example, DNAse I digests double-stranded DNA (dsDNA) and S1 nuclease acts only on single-stranded DNA (ssDNA). DNase I can be used to specifically degrade DNA in nucleic acid mixtures when only RNA is of interest. RNAses are very stable enzymes that are common laboratory contaminants.

Restriction endonucleases are found in bacteria; these enzymes prevent replication of foreign DNA.[90] Their action is sequence-specific, requiring recognition sequences of usually 4 to 10 nucleotides on a double-stranded DNA molecule. At each location where this sequence is found, the enzyme cuts both strands in a reproducible manner, resulting in either staggered or blunt-end cuts. For example, *EcoR*I is a restriction enzyme from *E. coli* that recognizes the 6-base sequence GAATTC and cuts between the G and the A on both strands, producing a staggered cut:

5′ . . . G/AATTC . . . 3′
3′ . . . CTTAA/G . . . 5′

Note that "blunt end" cuts would be produced if the enzyme hydrolyzed the bond between A and T.

Restriction enzymes are used for digesting large strands of DNA into smaller fragments and for preparing DNA from different sources to be joined together in cloning procedures. *Nicking enzymes* are restriction enzymes that cut only one strand of double-stranded nucleic acid.

Ligases catalyze the formation of phosphodiester linkages between two nucleic acid chains.[44] DNA ligases are not sequence-specific and require the presence of a

complementary template. In contrast, RNA ligases used in mRNA processing do not require a template but are sensitive to sequence.

Polymerases catalyze the synthesis of complementary nucleic acid polymers using a parent strand as a template.[43] In vitro, these enzymes can extend an oligonucleotide primer that is annealed to a template strand. Extension requires that the 3′OH of the extending end is free, and that nucleotide triphosphates (NTPs) are present. Extension stops if you run out of template or NTPs, or if no 3′OH groups are available at the extending end. Thermostable polymerases, such as *Thermus aquaticus (Taq)* DNA polymerase, are essential reagents for the automation of many nucleic acid amplification procedures.

Reverse transcriptase is found in retroviruses and catalyzes the synthesis of DNA from either an RNA or a DNA template.[5] Retroviruses have RNA genomes, and reverse transcriptase activity thus is required as part of their replication. In vitro, reverse transcriptase is used to make complementary DNA *(cDNA)* copies of RNA in samples and may be used for cloning, probe preparation, and nucleic acid assays.

AMPLIFICATION TECHNIQUES

Achieving adequate detection limits is a central concern for clinical applications of nucleic acid analysis. Techniques that increase the amount of either the target, the detection signal, or the probe are referred to as "amplification methods." Examples of amplification methods are listed in Table 37-1. In target amplification, the nucleic acid region around the area of interest is copied many times by in vitro methods. Areas outside the target are not amplified. In signal amplification, the amount of target stays the same, but the signal is increased by one of several methods, including sequential hybridization of branching nucleic acid structures and

TABLE 37-1 Amplification Techniques

Techniques	Amplification Type	Enzymes Needed	Thermal Cycling
Polymerase chain reaction (PCR)[85]	Target	DNA polymerase (thermostable)	Yes
Ligase chain reaction (LCR)[105]	Target	DNA ligase (thermostable)	Yes
Transcription-based amplification system (TAS)[47]	Target	Reverse transcriptase RNA polymerase	Yes
Transcription-mediated amplification (TMA)[40]; self-sustained sequence replication (3SR)[30]; nucleic acid sequence-based amplification (NASBA)[18]	Target	Reverse transcriptase RNA polymerase RNase H	No
Strand displacement amplification (SDA)[101]	Target	*Hin*cII DNA polymerase I (exonuclease deficient)	No
Loop-mediated amplification (LAMP)[71]	Target	DNA polymerase	No
Linked linear amplification (LLA)[81]	Target	DNA polymerase (thermostable)	Yes
Whole genome amplification (WGA) or multiple displacement amplification (MDA)[21]	Target	ϕ29 DNA polymerase	No
Antisense RNA amplification (aRNA)[77]	Target	T4 DNA polymerase Klenow S1 nuclease T7 polymerase	No
Branched DNA (bDNA)[17]	Signal	Alkaline phosphatase	No
Serial invasive signal amplification[32]	Signal	Cleavase	No
Q-beta replicase (QBR)[60]	Probe	Q-beta replicase	No
Rolling circle amplification (RCA)[6,59]; ramification amplification (RAM)[114]	Probe	T4 gene 32 protein ϕ29 DNA polymerase DNA ligase (RAM)	No
Isothermal oligo amplification[100]	Probe	*Bst*NBI nicking enzyme DNA polymerase (exonuclease deficient)	No

continuous enzyme action on substrate that may be recycled. Finally, in probe amplification the probe (or a product of the probe) is amplified only in the presence of the target. Amplification techniques can often achieve over a million-fold amplification in less than an hour.

Polymerase Chain Reaction (PCR) —Target Amplification

When the amount of target nucleic acid is increased by synthetic in vitro methods, target amplification is said to occur. The polymerase chain reaction (PCR)[85] is the best known and most widely applied of the target amplification methods. Because of the commercial availability of thermostable DNA polymerases, kits, and instrumentation, this method has been widely adopted in research and is also routinely used in the clinical laboratory.

Details of the PCR Process

PCR requires a thermostable DNA polymerase, nucleotides of each base (collectively referred to as *dNTPs*), the target sequence, and a pair of oligonucleotides (referred to as *primers*) complementary to opposite strands flanking the sequence to be detected. In the first step, target duplexes are denatured into single strands by heat (Figure 37-2). When the mixture is cooled, primers provided in great excess (usually over a million times the concentration of the initial target) specifically anneal to complementary sequences on the target. Once the primers are annealed, the action of the polymerase synthesizes two additional DNA strands containing the primers as the 5′ ends. The primers are placed close enough together so that the polymerase extends each strand far enough to include the priming site of the other primer. Usually, the optimal temperature for polymerization is at an intermediate temperature between the denaturation and annealing temperatures. The second cycle also begins with denaturation, but now there are twice as many strands (the original genomic DNA and the extension products from the first cycle) available for primer annealing and subsequent polymerization or extension. The temperature cycling is continued among (typically) three temperatures: a high temperature sufficient to denature the target sequence, a low temperature that allows annealing of the primers to the target, and a third temperature optimal for polymerase extension. The instrument that takes samples through the multiple steps of changing temperature is known as a *thermocycler.*

Repetitive thermocycling results in the exponential accumulation of the short product (consisting of primers and all intervening sequences). If the efficiency of each cycle is optimal, the number of target sequences doubles each cycle (efficiency = 2.0). PCR efficiency depends on the primers and the temperature-cycling conditions, along with the

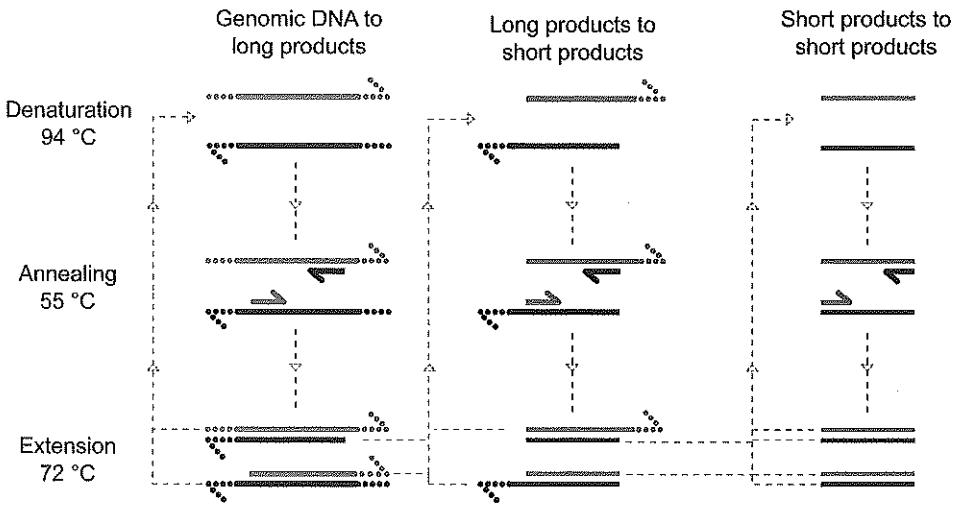

Figure 37-2 Schematic diagram of the polymerase chain reaction (PCR). Repetitive cycles of denaturation, annealing, and extension are paced by temperature cycling of the reaction. Two primers (indicated as short segments) anneal to opposite template strands (long gray and black lines) to define the region to be amplified. Extension occurs from the 3′-ends (indicated with half arrow heads). In each cycle, genomic DNA is denatured and annealed to primers that extend in opposite directions across the same region, producing long products of undefined length. Long products generated by extension of one of the primers anneal to the other primer during the next cycle, producing short products of defined length. Any short products present also produce more short products. After n cycles, up to 2^n new copies of the amplified region are present [n long products and (2^n − n) short products] plus 1 (original) genomic copy. A similar approach can be used to amplify RNA targets by initial reverse transcription of the RNA template to produce the DNA template.

presence or absence of polymerase inhibitors. Amplified products accumulate exponentially in the beginning cycles of PCR. At some point, however, the efficiency of amplification falls and, eventually the amount of product plateaus (Figure 37-3) either from exhaustion of components or from competition between primer and product annealing (i.e., the single strands of product are at such high concentrations that they anneal to each other rather than to the primers). The S-curve shape is similar to the logistic model for population growth. In a typical PCR reaction using 0.5 μM of each primer, the maximum DNA concentration achievable is about 10^{11} copies/μL.

With the addition of an initial reverse-transcriptase step to form cDNA from RNA in the sample, RNA targets can also be successfully amplified into DNA copies. The reverse transcription and DNA amplification steps are usually catalyzed by two different polymerases, but some thermostable enzymes (such as the *Tth* polymerase) have both DNA polymerase and reverse transcription activities, so that both steps can be performed in the same tube with the same enzyme.

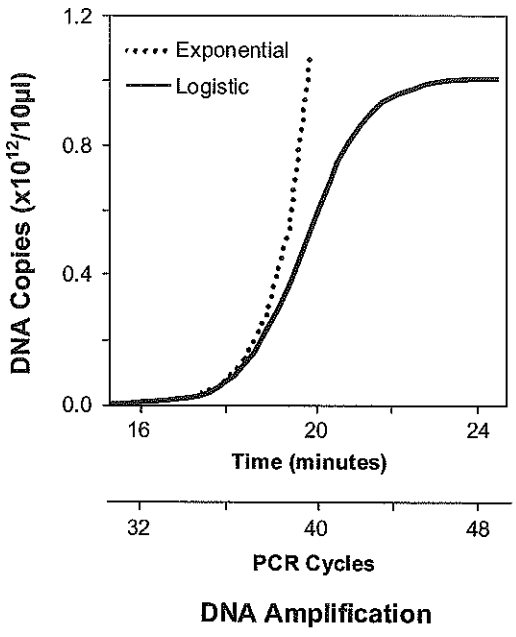

Figure 37-3 Exponential and logistic curves for DNA amplified by PCR. A doubling time of 30 seconds is assumed for PCR. That is, given the equation $N_t = N_0 e^{rt}$, in which N_t is the amount of DNA at time t and N_0 is the initial amount of the DNA, r is 1.386 min^{-1} for PCR. A carrying capacity of 10^{11} copies of PCR product per μL was used assuming that the reaction is primer limited at one third the primer concentration (initially at 0.5 μM, or 1×10^{11} primer molecule pairs per μL). Starting with only one target copy, it takes only 23 minutes (46 cycles) to amplify the target to saturation. *(Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In Persing DH, Tenover FC, Versalovic J, Tang YW, Unger ER, Relman DA, White TJ (eds.), Molecular Microbiology: Diagnostic Principles and Practice, Washington, DC: ASM Press, 2004:71-84. © 2004 ASM Press.)*

After amplification, the products can be detected by various methods. Simple gel electrophoresis with ethidium bromide staining may suffice. When greater accuracy is required, one of the primers can be fluorescently labeled so that after PCR the fragments are accurately sized on a *DNA sequencing* device. Alternatively, some form of hybridization assay can be used to verify or analyze the amplified product. Automated methods are always attractive and closed-tube methods are particularly advantageous in the clinical laboratory. Adding a fluorescent dye or probe before amplification allows thermocyclers equipped with optical detection to analyze the reaction as it progresses (real-time PCR) or after the reaction is complete (endpoint measurement) without need to process the sample for a separate analysis step.

PCR Kinetics and Rapid Cycling

It is natural to think about PCR in terms of three events—denaturation of double-stranded target, annealing of target and primers, and extension of the DNA strand from the primer—occurring at three temperatures, each requiring a certain amount of time. Indeed, it is common to perform PCR by holding the reaction mixture at three different temperatures (for instance, denaturation at 94 °C, annealing at 55 °C, and extension at 72 °C). Standard thermocycling instruments that use conical tubes focus on accurate temperature control of the heating block at equilibrium, not on the dynamic control of the sample temperature. As a result, sample temperatures are not well defined during transitions, and long cycle times have become standard to ensure that the sample reaches target temperatures. Reproducibility between instruments and manufacturers is poor and PCR often takes 2 to 4 hours to complete a typical 30-cycle amplification.

The kinetics of PCR suggest that *rapid transitions* between temperatures and *continuous* changing of temperature (i.e., with minimal or no pauses in the rate of change of temperature to create temperature plateaus) provide a better paradigm of PCR amplification (Figure 37-4). Denaturation, annealing, and extension are very rapid reactions as shown by experiments in capillaries.[107] The use of temperature "spikes" at denaturation and annealing, instead of extended temperature plateaus, allows for rapid cycling with the appropriate instrumentation. The actual time required for PCR depends on the size of the product, but when it is less than 500 bp, a 30-cycle amplification is easily completed in 15 minutes. Furthermore, rapid amplification improves specificity. Consider PCR amplification of a 536 bp fragment of β-globin amplified at different cycling speeds (Figure 37-5). With conventional slow cycling, many nonspecific products are generated (cycling profile A). These products disappear as the cycling time is decreased (profiles B, C, and D). In fact, amplification yield and product specificity are optimal when denaturation and annealing times are minimal.

Initial denaturation of genomic DNA may be required before PCR cycling, depending on how the DNA sample was prepared. Either boiling the sample or an initial

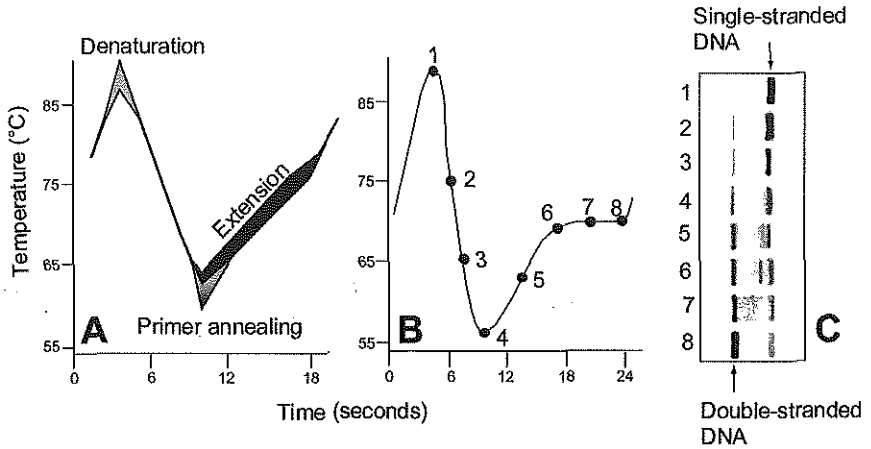

Figure 37-4 A visual demonstration of PCR kinetics. The three phases of PCR (denaturation, annealing, and extension) occur as the temperature is continuously changing (panel A). Toward the end of PCR temperature cycling, the reaction contains single- and double-stranded PCR products. When different points of the cycle are sampled (by snap-cooling the mixture in ice water, panel B) and analyzed, the transition from denatured single-stranded DNA to double-stranded DNA is revealed as a continuum (panel C). Progression of the extension reaction can be followed by additional bands appearing between the single- and double-stranded DNA (time points 5 to 7). *(Modified with permission from Wittwer CT, Herrmann MG: Rapid thermal cycling and PCR kinetics. In: PCR Applications. M Innis, D Gelfand, J Sninsky, eds., San Diego: Academic Press, 1999:211-229. © 1999 Academic Press.)*

denaturation step of 5 to 10 seconds before PCR cycling may be necessary. During PCR, however, there is no need to hold the denaturation temperature at all. Even for long PCR products, denaturation is complete in less than 1 second after the denaturation temperature is reached. Anything greater than a denaturation time of "0" only serves to degrade the polymerase. If longer denaturation times are required, either the sample is not reaching temperature or heat-activated polymerases are being used.

Product specificity is optimal when annealing times are less than 1 second. Longer annealing times may be required if the primer concentrations are low. The required extension time for each cycle depends on the length of the PCR product. Extension is not instantaneous, although it is much faster than common practice would suggest. Extension rates of *Taq* polymerase under optimal conditions are 50 to 100 bases per second. Use of a 5 to 10 minute final extension is not rational. Products can be as small as 40 bp to about 40 kb. To amplify products longer than 5 kb, mixtures of polymerases that include some 3′-exonuclease activity to edit mismatched nucleotides are usually used.

Instead of separate annealing and extension temperatures, both processes can be carried out at the same temperature, resulting in two-temperature, instead of three-temperature, cycling. Although this simplifies the demand on instrumentation and programming, it limits the choice of primers and requires a longer extension time at suboptimal temperatures.

PCR Optimization and Primer Design

In addition to the temperature-cycling conditions, the specificity of PCR depends on the choice of primers and the Mg^{++} concentration. The choice of primers often dictates the quality and success of the amplification reaction. To select primers, the sequence of the target must be known. Some guidelines for primer selection are intuitive and helpful:

1. Avoid primers that anneal to themselves or to other primers. Particularly avoid complementarity at the 3′-end of primers, and especially do not use a primer that has reciprocal 3′-end complementation.
2. Choose primers that are specific to your target. Avoid simple sequence repeats and common repeated sequences, such as *Alu* repeats. If your target has close relatives, design your primers so that they will anneal only to your intended target. Targets that you want to avoid include pseudogenes (for genomic DNA) and related bacterial or viral strains (for microorganisms).
3. Avoid primers that have sequence complementary to internal sequences of the intended product, especially at the 3′-ends of the primers.
4. Use primers between 18 and 25 bases that are matched in melting temperature (Tm) to each other. A primer greater than 17 bases long has a good chance of being unique in the human genome.
5. Unless you have a reason to amplify longer targets, choose a product length less than 500 bases. Shorter products amplify with higher efficiency.

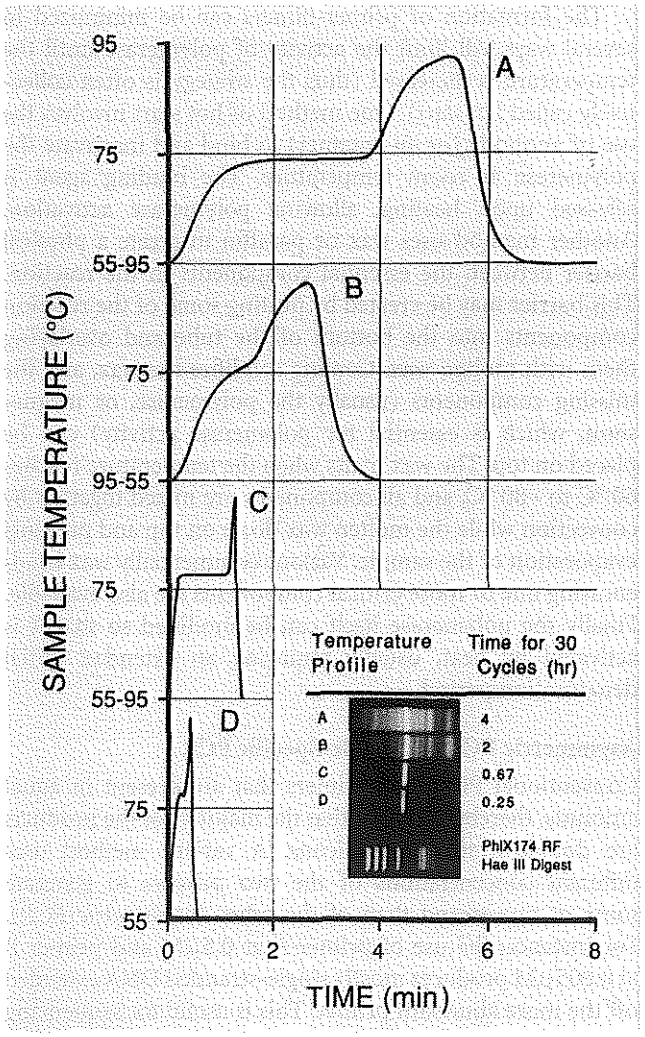

Figure 37-5 Rapid PCR improves product specificity. Samples were cycled 30 times through profiles A, B, C, and D. Increased specificity of amplification of a 534 bp β-globin fragment is seen with faster cycles (C and D). *(Reprinted by permission of the publisher from Wittwer CT, Garling DJ: Rapid cycle DNA amplification: time and temperature optimization. BioTechniques 1991, 10:76-83. © 1991 Eaton Publishing.)*

6. As a final test, do a search for sequences similar to your primers that are present in the background DNA likely to be present in your assay (http://www.ncbi.nlm.nihgov/BLAST/). Many primer selection programs are available, both commercially and freely obtained over the Internet. However, none of the selection rules used have been empirically tested.

With the human genome sequenced, it should be possible to vastly improve primer selection. Given two primers, an entire genome search for mispriming sites could rule out primer pairs with the potential to produce undesired PCR products. For exponential PCR, priming sites must be oriented appropriately within a close distance. The desired target can be favored by choosing a small product size and rapid cycling.

Detection Limits of PCR

When PCR is performed under optimal conditions, a single copy of the target can be detected. At the end of a 30-cycle amplification, a single target molecule in a tube will multiply up to a billion copies. In reality, however, we need to take into account the statistical probability of getting that single copy into the reaction tube as determined by the Poisson distribution. If a dilute solution of template is distributed among test tubes such that, on average, one target copy will be present per tube, 37% of the tubes will have no target, 37% will have one target, and the remainder will have more than one. If there is an average of two copies per tube, approximately 14% of the tubes will have no template and will provide a false-negative result. About five copies on average are necessary for 99% of the tubes to include at least one copy. This limitation of low copy analysis holds true for any amplification technique.

3′-end of PCR Products

Taq DNA polymerase and other polymerases have a terminal transferase activity that results in the nontemplated addition of a single nucleotide to the 3′-ends of PCR products. In the presence of all four dNTPs, dATP is preferentially added. This means that some percentage of the double-stranded products generated by PCR will not have blunt ends but a protruding A at the 3′-end. Although this does not influence most detection protocols, it can complicate some systems with high detection sensitivity and size resolution. On the other hand, this feature is useful for high-efficiency cloning and ligation of PCR products.[117]

Contamination Control for PCR (False-Positive Results)

Because PCR can detect a single molecule of target sequence, a small amount of contamination in a sample can easily produce a false-positive result. The greatest potential for contamination comes from the product of the amplification reaction, referred to as the *amplicon* (used interchangeably with *PCR product*). After amplification, each reaction mixture may contain as many as 10^{12} copies of the amplicon. Thus minute aerosol droplets contain more than enough target for robust amplification. Amplicon can contaminate reagents, pipettes, and glassware. It is easy to turn a laboratory into a Dr. Seuss fiasco.[89] Experience has dictated the use of laboratory procedures that minimize contamination by amplicons.[49] These include the use of physically separated areas for preamplification and postamplification steps, positive-displacement pipettes to minimize aerosol contamination, and the use of prealiquoted reagents. The most effective way of all is to not let the product out of the tube. Methods that perform amplification, detection, and characterization in a closed tube eliminate the risk of product contamination. Even with these precautions, a negative control

or blank (all reactants minus target DNA) is one of the most important controls for PCR.

In combination with the precautions listed above, chemical modifications can be made to the amplicon so it becomes an unsuitable template for further amplification. One of the commonly practiced chemical modifications is to substitute deoxyuridine 5′ triphosphate (dUTP) for deoxythymidine 5′ triphosphate (dTTP) in amplification reactions, which results in incorporation of U in place of T in the amplified product. A bacterial enzyme, uracil-*N*-glycosylase (UNG), degrades DNA that contains U. Because U is not normally found in DNA, only amplicons will be susceptible to degradation by UNG treatment. During a brief incubation step before amplification, uracil-containing DNA strands that are carried over from previous amplifications are enzymatically degraded and cannot serve as substrates for further amplification. UNG is then inactivated during the first denaturation cycle, so newly formed amplicon can accumulate normally during the reaction. However, UNG may regain activity, even after multiple cycles of amplification, if the temperature of the reaction mixture drops below 55 °C. Residual UNG activity may also affect the detection limit (and the sensitivity of quantitative PCR assays) if amplified products are held at room temperature before detection.

Inhibition Control for PCR (False-Negative Results)

PCR is a resilient process and does not require highly purified nucleic acid. In practice, however, clinical samples may contain unpredictable amounts of impurities that can inhibit polymerase activity. To ensure reliable amplification, some form of nucleic acid purification is often used. The idiosyncratic nature of PCR inhibitors within clinical specimens requires demonstration that the sample (or preparation of nucleic acid purified from it) will allow amplification. A control nucleic acid sequence, usually different from the target, can be added to the sample (or extract from the sample). Failure to amplify this control indicates that further purification of the sample is required to remove inhibitors of the reaction.

Hot Start Techniques

PCR sensitivity and specificity can be compromised by the formation of unintended low molecular weight artifacts. This process is initiated before PCR when the primers, template, and polymerase are all together at temperatures below the annealing temperature of PCR. Even at low temperatures, if a primer momentarily anneals to another primer or to an undesired target region, *Taq* DNA polymerase may extend the complex. If the extension product, in turn, is primed and extended, then unintended, double-stranded products can be formed (e.g., primer dimers) that serve as amplification templates throughout the reaction. Primer-dimers can be distinguished from the intended target by their molecular weight or melting temperature, but they also influence the efficiency of the intended amplification and decrease the sensitivity of the assay.

The formation of primer-dimers can be minimized in several ways. All limit the activity of polymerase until the temperature is increased (thus the strategy is often collectively called *hot start*). One method of hot start involves the use of antibody (or an aptamer) to bind and inactivate the polymerase at room temperature. The binding agent is released upon heating, allowing polymerase activation. Another method uses wax or paraffin to create a physical barrier between the essential components in the reaction. This barrier may be created by putting some of the reaction components into the bottom of the tube and overlaying them with molten wax. Cooling solidifies the wax, and the missing components (usually the polymerase, or magnesium, which is essential for polymerase activity) can be placed on top. The wax melts when the temperature reaches 60 °C to ~80 °C, and all components are mixed together by convection while the molten wax floats on top and prevents evaporation of the sample. Various commercially wax beads encasing one or more critical components are also available. Finally the polymerase itself can be modified so that it is activated by heat, usually requiring an extended initial denaturation period.

Asymmetric PCR and Allele-Specific PCR

Conventional PCR uses primers that are present in equal amounts, thereby ensuring that the majority of the products are double-stranded amplicons. A variant method uses different concentrations of the two primers to generate more of one strand than of the other *(asymmetric PCR)*. For instance, the use of primer A at 0.5 μM and primer B at 0.005 μM produces mostly single-stranded DNA extended off the more abundant primer. This is useful for sequencing purposes or making single-stranded probes. Yield of the product, however, may be low. With less extreme ratios (e.g., primer A at 0.5 μM and primer B at 0.2 μM), the yield is mostly preserved, with one strand produced in enough excess to make it more available for probe hybridization.

Another variant method called *allele-specific PCR* enables preferential amplification of one genetic allele over another. The 3′-end of one primer is placed at the polymorphic site and is extended only if it is completely complementary to the target. This strategy is used for distinguishing a gene from its pseudogenes and for genotyping of SNPs. Allele-specific PCR is also the most common method used for determining haplotypes.[63]

Other Forms of Target Amplification

A large number of other methods of target amplification have been described. Short descriptions of some of these methods follow, with citations of sources of further information.

Ligase Chain Reaction

The ligase chain reaction (LCR)[105] uses four oligonucleotides and a DNA ligase. Two of the oligonucleotides anneal

directly adjacent to each other on the target. When they are joined (ligated), they form a target for the remaining two oligonucleotides (and vice versa). As in PCR, temperature cycling is used and the target is ideally doubled each cycle. The ligase chain reaction requires that the exact sequence of the region to be amplified is known.

Transcription-Based Amplification Methods

Transcription-based amplification methods are modeled after the replication of retroviruses. These methods are known by various names including nucleic acid sequence–based amplification (NASBA),[18] transcription-mediated amplification (TMA),[29,40] and self-sustained sequence replication (3SR) assays.[30] Isothermal target amplification, using the collective activities of reverse transcriptase, RNase H, and RNA polymerase, is common to these methods. As illustrated in Figure 37-6, the method may be applied to single-stranded RNA or double-stranded DNA targets. A reverse transcriptase is used to synthesize a cDNA strand from the template RNA with a primer that has an RNA polymerase promoter sequence as a 5′-tail. The RNA strand of the RNA/DNA duplex is then digested with RNAse H, followed by synthesis of double-stranded DNA with an opposing primer. The promoter sequence on the double-stranded DNA then promotes transcription of multiple copies of single-stranded RNA by the RNA polymerase, completing the cycle. As in PCR, all reagents can be included in one mixture and amplification is exponential with completion in less than an hour. Unlike PCR, these methods do not require temperature cycling (except for an initial heat denaturation if a DNA template is used). The method is particularly advantageous when the target is RNA (e.g., HIV and HCV in blood bank nucleic acid testing).

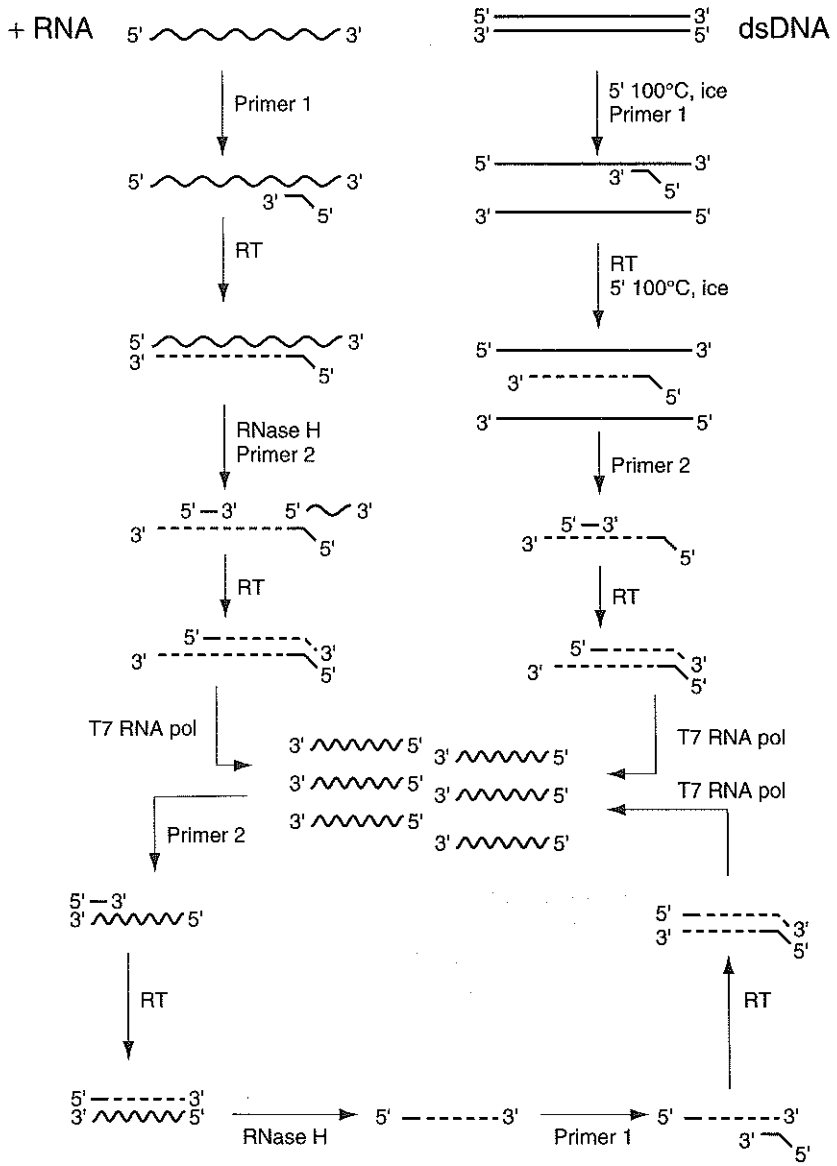

Figure 37-6 Schematic diagram of the nucleic acid sequence–based amplification (NASBA) method applied to single-stranded RNA and double-stranded (ds)DNA. The method is based on an extension of primer 1 (containing a T7 promoter) by reverse transcriptase (RT), degradation of the RNA strand by RNase H (or heat denaturation for double-stranded DNA), synthesis of the second strand of DNA by reverse transcriptase, and RNA synthesis by T7 RNA polymerase (pol). With RNA synthesis, the system enters the cyclic phase. *Solid lines*, DNA; *dashed lines*, newly synthesized DNA; *wavy lines*, RNA. *(Reprinted by permission of the publisher from vanGemen B, Kievits T, Nara P, et al.: Qualitative and quantitative detection of HIV-1 RNA by nucleic acid sequence-based amplification. AIDS, 7(Suppl 2):S107-S110, 1993. © 1993 Rapid Science Publishers.)*

Strand Displacement Amplification

Another isothermal amplification technique is strand displacement amplification (SDA).[101] After heat denaturation of DNA in the presence of four primers, dCTP, dGTP dUTP, and a modified deoxynucleotide (dATPαS), two enzymes are added, an exonuclease-deficient polymerase and a restriction enzyme. The two flanking primers that enter into exponential amplification have a restriction site added to their 5′ end and get nicked by the restriction enzyme, allowing displacement of strands that can in turn be primed, extended, and nicked. Deoxy-ATPαS is used so that the restriction sites include a hemiphosphorothioate linkage to allow single-strand nicking, instead of cutting through double strands.

Loop-Mediated Amplification

The target amplification methods presented so far produce a defined length of RNA or DNA according to the placement of the primers. In loop-mediated isothermal amplification (LAMP), multiple populations of repeated DNA structures in the shape of a stem and loop (stem-loops) are produced, and concatenated structures of variable length and branching are generated.[71] After DNA denaturation, the process is isothermal, requiring four primers and a polymerase. Two of the primers each recognize two distinct sequences on the target DNA, resulting in loops forming at the end of extension products. Repeated strand displacement DNA synthesis results in the final mixture of products.

Linked Linear Amplification

If two PCR primers include elements that cannot be replicated, an exponential expansion is reduced to arithmetic accumulation. However, if multiple nested sets of internal primers (also nonreplicable) are included, product accumulation (at least in theory) can approach that of PCR. This process is known as linked linear amplification. It requires a polymerase, several sets of nested primer pairs, and thermal cycling similar to PCR.[81]

Whole Genome and Whole Transcriptome Amplification

Instead of specific amplification of one target to improve sensitivity, methods that amplify all genomic DNA or mRNAs are useful when the target is in short supply. For example, *multiple-displacement amplification* uses exonuclease-resistant random hexamers and a highly processive polymerase to amplify DNA nonspecifically.[21] Initial DNA denaturation is not necessary and the reaction proceeds isothermally. Similarly, messenger RNA can be generically amplified with a poly(T) primer modified with an RNA polymerase promoter.[77] After reverse transcription, second-strand DNA synthesis, and transcription, antisense RNA is produced. Both whole genome and antisense RNA amplification are also useful as nucleic acid purification methods before amplification or detection.

Other Approaches to Amplification

It is not always necessary to amplify the target DNA sequence or a cDNA sequence complementary to an RNA target. Instead of target amplification, both signal amplification and probe amplification can be used.

Signal Amplification: Branched-Chain DNA

Instead of increasing the concentration of target, signal amplification techniques use nucleic acids to magnify the detection signal. The branched-chain DNA (bDNA) method is one of these techniques in common use. The bDNA approach hybridizes the target nucleic acid to multiple capture probes affixed to a microtiter well.[99] This is followed by hybridization to a series of "extender," "preamplifier," and amplifier probes. The final, highly branched amplifier probe includes multiple copies of signal-generating enzymes that act on a chemiluminescent substrate to produce light. The use of nucleotide analogs isoC and isoG may be used to increase specificity of the signaling cascade.

Serial Invasive Amplification

When two probes overlap on one target, an "invasive" cleavage reaction can be catalyzed by certain structure-specific nucleases. The cleaved fragment, in turn, can cause invasive cleavage of a secondary probe in the shape of a hairpin. The hairpin probe can be designed as a fluorogenic indicator by using a reporter/quencher pair of dyes that are separated by cleavage. This serial sequence of events (primary invasion and cleavage, followed by secondary invasion and cleavage of an indicator probe) is known as the serial invasive signal amplification reaction.[32] After DNA denaturation, cooling, and the addition of enzyme are completed, the reaction is run at a temperature at which both the primary and secondary reactions recycle.

Probe Amplification—Q-beta Replicase

Q-beta replicase is a method in which the concentration of probe increases if the target is present. Similar to target amplification, a large amount of nucleic acid product makes detection much easier. An RNA probe is replicated exponentially in the presence of the RNA-directed RNA polymerase, Q-beta replicase.[60] The probe is a recombinant RNA hybrid that includes sequence complementary to the target embedded in a naturally occurring template for the enzyme.

Rolling Circle Amplification

If a primer is annealed to a closed circle of DNA in the presence of a processive, displacing polymerase, the complement of the circle will be synthesized over and over again with displacement of the tandem repeats.[59] If two primers are used in opposite orientation, progressively more complex branches will be formed in an exponential reaction. Rolling circle amplification is triggered by formation of the circle by

ligation of the two ends of a linear probe on template DNA. Ligation may happen directly, after polymerization through a gap, or after annealing of an additional, allele-specific oligonucleotide.

Isothermal Oligo Amplification

Short oligonucleotides, 8 to 16 bases in length, can be linearly produced at a constant temperature in the presence of a polymerase and a nicking enzyme.[100] The replication can be exponential if the amplification template is in excess and contains two complementary copies of the signal oligonucleotide. The signal oligonucleotide, or trigger, is originally produced by hybridization of a "trigger template" to the target, generating the oligonucleotide trigger by extension and nicking.

Endpoint Quantification in Amplification Assays

Amplification assays can produce both qualitative answers (yes/no, more or less abundant than reference materials) and quantitative answers (the original concentration of target sequence in the sample). In order to use the amplification process for quantitative assessments, many variables need to be carefully controlled. Variations in extraction efficiency, presence of enzyme inhibitors, lot-to-lot variation in enzyme and reagent performance, and day-to-day variation in reaction and detection conditions need to be addressed in methods that attempt to yield a quantitative result.

Quantitative analysis at the end point of amplification is usually carried out by use of calibrators with known amounts of target or a target-mimic. Quantification of sample nucleic acid may be determined by comparison with an *internal standard* of known amount that is added at the time of sample processing to control for efficiency of nucleic acid purification. These internal standards can be DNA fragments, plasmids, or RNA packaged into synthetic phage or virus particles to mimic the assay of real viruses (so called *armored RNA*[102]). One such strategy uses a *competitor* template, which is amplified by the target primers but generates an amplicon with sequence or size different from that of the expected amplicon. This competitor template is added in varying amounts to replicates of the sample before amplification. When the target and competitor are present at equal concentrations, the amounts of the two different products will also be the same. The competitor is present in the same tube as the sample, so any variation in enzyme activity affects both products identically. This method is not frequently used in clinical applications because of the requirement for multiple assays on each patient sample.

Real-time PCR is a simpler and more powerful approach to quantification than endpoint assays. The reaction is monitored each cycle, and the profiles of the curves are used to calculate initial target concentrations. Real-time PCR is described in further detail in later sections of this chapter.

DETECTION TECHNIQUES

Molecular diagnostics creates requirements for detection techniques used in two rather different tasks:

- Generic measurement or visualization of nucleic acid
- Discrimination and measurement of specific nucleic acid sequences

The latter task usually involves the use of reporter molecules and labeled probes.

Generic Measurement and Visualization of Nucleic Acids

To measure or visualize nucleic acids generically, two approaches are used: ultraviolet absorbance and dye staining.

UV Absorbance

Nucleic acid molecules absorb ultraviolet light maximally at 260 nm owing almost entirely to the constituent bases. This property can be used to measure the nucleic acid content of a solution. DNA double helices have lower molar absorptivity than would be measured from the equivalent number of nucleotide monomers, and when DNA is denatured into single strands (ssDNA) (e.g., by extremes of heat or pH) absorptivity increases.[72] If a double-stranded DNA preparation is pure, a 50 mg/L solution has an absorbance of 1.0 at 260 nm. Single-stranded nucleic acids (DNA or RNA) have a greater absorbance, so only about 30 mg/L gives an absorbance of 1.0. More precise estimates for oligonucleotides are based on dinucleotide contributions reviewed later in this chapter. It is common to assess the purity of a nucleic acid preparation by its ratio of absorbances at 260 nm and 280 nm *(260:280 ratio)*. In contrast to nucleic acids, proteins absorb maximally at 280 nm. A pure preparation of nucleic acid should have a 260:280 ratio of 1.7 to 2.0. Lower values suggest significant protein contamination.

Fluorescent Staining of Nucleic Acids

Although absorbance measurements are simple and precise, they are not sensitive. Fluorescent stains that bind to nucleic acid are 1000 to 10,000 times more sensitive than absorbance measurements. The best known example of a nucleic acid dye is ethidium bromide, a positively charged, intercalating dye for double-stranded DNA and to a lesser extent, single-stranded DNA and RNA. Cyanine dyes, such as SYBR Green I, are also popular stains for nucleic acids, as they do not fluoresce unless they are bound to nucleic acids, thus providing very low background. With the appropriate optics, single molecules of DNA can be visualized with cyanine-based nucleic acid stains.[75] Nucleic acid dyes can detect DNA and RNA in gels, or in solution (such as in real-time PCR).

Reporter Molecules and Labeled Probes

Ultraviolet absorbance and fluorescent dyes in themselves do not discriminate between different nucleic acid sequences

(i.e., they are not sequence-specific). Specificity in nucleic acid assays almost always comes from the hybridization of two complementary nucleic acid strands. Many reporter molecules can be covalently attached or incorporated into nucleic acid probes. The use of these probes can reveal the physical presence or location of sequences complementary to the nucleic acid portion of the probe.

Radioactivity

The first probes used in nucleic acid detection were radioactively labeled. Radioactive labels are still favored in some research settings because of the sensitivity obtained with probes of high specific activity. The most frequently used isotopic labels are ^{32}P and ^{33}P, which are incorporated into the probe by enzymatic reactions. *Nick translation* is a classical method of labeling double-stranded DNA fragments. Nicks are introduced randomly into each strand of DNA by DNase I, and the resulting 3′-OH groups form priming sites for DNA polymerase. Labeled nucleotides are incorporated as the polymerase extends the strand by digesting and removing the unlabeled strand. Another method of labeling double-stranded DNA is *random priming*, in which the nucleic acid is denatured and allowed to anneal with short hexamer oligonucleotides of random sequence. The 3′ end of an annealed hexamer forms the initiation site for the DNA polymerase, which incorporates labeled nucleotides using single-stranded regions of the DNA as the template. Labeled nucleic acid can also be synthesized by PCR, or if a labeled RNA is desired, it can be prepared by use of a double-stranded DNA fragment containing a promoter sequence for RNA polymerase and incorporating radiolabeled ribonucleotides by transcription.

Additional enzymatic reactions are useful for labeling oligonucleotides. T4 polynucleotide kinase may be used to label the 5′ end of an oligonucleotide with ^{32}P or ^{33}P. Alternatively, terminal deoxynucleotidyl transferase (TdT) can be used to add labeled nucleotides onto the 3′ end in a *tailing* reaction. No template is required, and the number and type of nucleotides can be controlled by the reaction conditions. This results in a somewhat longer probe than the original oligonucleotide, with additional labeled bases at the 3′ end. The sensitivity that is achieved with radioactive nucleic acid probes is largely determined by the extent of incorporation of the radiolabel. Radioactively labeled probes have a short half-life limited by isotopic decay and radiolysis of the nucleic acid. This inherent instability, along with concerns of radioisotope safety and disposal, restricts the use of radioactive probes in the clinical laboratory. (See Chapter 1 for further descriptions and discussion of radioactivity.)

Indirect Probe Detection

The first practical example of nonisotopic probe labeling used a biotin-labeled analog of dUTP.[52] Despite the altered steric configuration, this nucleotide is incorporated by both DNA polymerase and terminal transferase. Other functional groups, such as digoxigenin, may also be used as affinity labels through chemical linkage to a dUTP and incorporation into polynucleotides. Alternatively, oligonucleotide probes can be labeled during synthesis with biotin or amino linkers for subsequent attachment to indicator molecules. Labels at either the 5′ or 3′ end of the molecule are usually preferred because central modifications may interfere with hybridization.

Biotin and other affinity labels do not generate detectable signals on their own. However, they can initiate signal amplification mediated by high-affinity binding with antibodies, or in the case of biotin, with avidin or streptavidin. These binding molecules can be linked to enzymes—such as horseradish peroxidase or alkaline phosphatase—connecting a single target to a single enzyme. Enzyme activity is monitored according to the enzyme substrate used (chemiluminescent, colorimetric, or fluorescent).

Affinity labels can be used to capture and localize targets to an area of a solid support. For example, biotinylated probes can be affixed to a streptavidin-coated surface. After incubation with the target nucleic acid, a second probe is added, which is either directly labeled with fluorescence or conjugated through an affinity label to an enzyme. Any background or nonspecific localization of reagents results in amplification of an undesired signal along with the desired signal, and these methods usually require multiple separation and washing steps to decrease the background.

Nucleic acids can also be linked to organic indicator molecules that emit light when exposed to certain chemicals (chemiluminescence). For example, when acridinium esters are exposed to hydrogen peroxide at high pH, light is emitted.[69] Bioluminescence occurs when biomolecules produce light through catalysis of certain substrates. Alkaline phosphatase and peroxidase are examples of enzymes that can act on luminescent substrates to emit light. Luciferase is another example of a bioluminescent molecule. Luciferase has been used as an indicator of ATP generation in pyrosequencing (see the Alternatives to Electrophoresis section later in this chapter). Electrochemiluminescence is initiated at an electrode surface in the presence of certain chelates of ruthenium (II). Once activated by charge transfer, chemiluminescence occurs.[10] For further discussion of these detection techniques, see Chapter 3 on Optical Techniques.

Fluorescent Labels

Advances in oligonucleotide synthesis and fluorescence detection systems have made fluorescently labeled probes the preferred reporter for nucleic acid analysis. Many fluorescent labels are now available, allowing color multiplexing for applications such as DNA sequencing, fragment length analysis, DNA arrays, and real-time PCR (all reviewed later in this chapter). Techniques such as fluorescence polarization, fluorescence resonance energy transfer (FRET), and fluorescence quenching can provide additional detection

specificity. Fluorescence polarization can be used to distinguish free from bound label, if the molecular rotation of the probe changes upon binding.[48] Molecular rotation primarily depends upon the size of the molecule, so binding of a small probe onto a large target results in a polarization increase that can be measured. FRET techniques depend on the distance between two spectrally distinct fluorescent labels. The two labels are either brought closer together through hybridization, or end up farther apart, often through hydrolytic cleavage of a dual-labeled probe.[109] Finally, fluorescence quenching or augmentation can occur with hybridization of a fluorescent oligonucleotide to its target. The effect depends on the specific fluorescent dye and the inherent quenching from G residues in the target and/or probe.[19,67] Alternatively, quenching moieties can be purposely incorporated into the probe.[54,97] For further discussion, see Chapter 3, Optical Techniques.

Electrochemical Reporters

Electrochemical detection of nucleic acids is an area of continued research. A hybridization event can be detected by a redox indicator molecule that recognizes the DNA duplex, or by other hybridization-induced changes in electrochemical parameters, such as conductivity or capacitance. (See Chapter 4 for further discussion of electrochemistry and sensors.) One design attaches an oligonucleotide to an electrode surface. If the complementary target is present, it binds to this oligonucleotide and to an electroactive reporter oligonucleotide labeled with ferrocenyl derivatives that can be detected by voltammetry.[98] Another design also uses a tethered oligonucleotide, a target, and a reporter probe, although the reporter probe is attached to a metal nanoparticle that changes the conductivity between electrodes.[74] Although labeled probes are usually used, detection with unlabeled probes has also been demonstrated. An unlabeled oligonucleotide anchored to a field-effect sensor can be used to detect hybridization to the target by an increase in the local charge.[25] Although the techniques are very interesting, it is difficult to make electronic methods sensitive and specific enough so that nucleic acid amplification is not required.

DISCRIMINATION TECHNIQUES

Three general categories of nucleic acid discrimination techniques will be reviewed:

- Electrophoretic separation: Provides physical separation of individual nucleic acid species based on molecular weight and shape.
- Alternatives to electrophoresis: Determines the size or sequence of nucleic acid without use of electrophoresis. Examples are high-performance liquid chromatography (HPLC) and mass spectrometry.
- Hybridization assays: Provides visualization of specific nucleic acids out of a background, usually by use of probes.

Some techniques use both electrophoresis and hybridization.

ELECTROPHORESIS

Electrophoresis is the most commonly used method for DNA and RNA analysis. Both DNA and RNA are negatively charged and will migrate toward the anode (the positively charged electrode) when an electrical field is present within an appropriately buffered solution. Separation of different nucleic acids occurs when mixtures are allowed to travel through a neutral sieving polymer under the electrical field. Separation is primarily based on molecular weight, with smaller molecules traveling faster through the polymer than larger ones (Figure 37-7). When very large molecules (≥50 kb) have to be separated, pulsed electrical fields are employed to help move these molecules through the polymer matrix.[61] Separation also occurs based on the physical conformation, or shape, of the molecule. For instance, single-stranded molecules may fold into secondary structures, and double-stranded molecules may form heteroduplexes, nicked or superhelical circular structures. Separation based on shape can provide useful information, but it can also confuse size-based analysis. For instance, because RNA generally has a high degree of secondary structure, electrophoresis of RNA is usually performed under denaturing conditions to abolish these structures. Electrophoresis of DNA is performed under nondenaturing or denaturing conditions depending on the application. The result of an electrophoretic separation provides the basis of interpretation of many clinical assays.

Agarose and *polyacrylamide* are the two types of polymers commonly used in electrophoresis. Several chemical variants of the polymers are commercially available and are tailored for different separation ranges and applications. The choice of polymer and polymer concentration (usually expressed as % w/v) is dictated by (1) the size of nucleic acid to be separated, (2) the resolution that is required, and (3) how you will visualize and analyze the result. Using various concentrations, an agarose gel can separate nucleic acid fragments as small as 20 bp to over 10 Mb (10,000 kb), including chromosomes of yeast, fungi, and parasites. But it is generally suited for low-resolution separation (2% to 5% differences in size). Agarose polymers are cast in trays (often commercially supplied as precast gels) and submerged in buffer. The gels are permeable to fluorescent nucleic acid–binding dyes, and results of electrophoresis are recorded by a photographic image of the stained gel under ultraviolet illumination.

Polyacrylamide polymers are suited for high-resolution separation (down to about 0.1% size differences) of short molecules (up to about 2 kb), and are the primary polymer for single-stranded nucleic acid separation, such as *DNA sequencing*. Polyacrylamide is used either as a linear polymer solution, which is filled in capillaries *(capillary electrophoresis)*, or as cross-linked gels, which are cast between two plastic or glass plates *(slab gel electrophoresis)*. Polyacrylamide gels are permeable to fluorescent stains, and also suitable for silver staining of nucleic acids. In addition, the optical clarity of polyacrylamide polymers makes them ideal for visualizing emission signals from fluorescently labeled fragments using laser-induced fluorescence detection.

Table 37-2 lists common electrophoresis-based techniques described further in this section.

Restriction Fragment Length Polymorphism

DNA extracted from a cell is extremely long, and is usually cut into shorter fragments before electrophoresis to aid the analysis. Restriction endonucleases cut double-stranded DNA into fragments of reproducible size; the same enzyme produces the same fragments in different specimens if the specimens contain the same DNA sequence. If an alteration in the DNA abolishes or creates a cleavage site recognized by the enzyme (or changes the spacing between two cleavage sites), then electrophoresis of digested fragments will reveal those changes (or polymorphisms) in fragment length: hence the name *restriction fragment length polymorphism* (RFLP).

PCR/RFLP

Many sequence alterations are on fragments that can be amplified by PCR, making RFLP analysis very simple. After PCR, the products are digested with one or more restriction enzymes and analyzed by electrophoresis. For example, if a sample has a mutation that disrupts an enzyme recognition site, this can be distinguished from a sample that does not have the mutation. Such an assay will produce one uncut PCR fragment when the mutation is present, and two shorter fragments when the mutation is absent (Figure 37-8). If the mutation is present as a heterozygote (one normal and one mutant copy of DNA), then one long and two shorter fragments will be observed. Usually it is possible to design the assay so that the fragments can be easily resolved by agarose electrophoresis and visualized by staining the gel with a fluorescent DNA-binding dye, such as ethidium bromide. One variant of this method uses reverse-transcribed mRNA, which lacks the introns that would be present in the DNA. In this way, multiple exons can be analyzed in one PCR reaction.

PCR Product Length Analysis

Some DNA alterations involve sequence insertions, deletions, rearrangements, and changes in the number of repeat sequences (such as STRs and VNTRs). If these alterations reside within a fragment that can be amplified reliably by PCR, then variation in the length of the amplified fragment will indicate these structural alterations. Enzyme digestion is

TABLE 37-2 Commonly Used Electrophoresis-Based Techniques

Techniques Using Electrophoresis	Detection/ Scanning of Polymorphisms
PCR/Restriction fragment length polymorphism (RFLP)	Detection
PCR (RT-PCR) fragment analysis	Detection
Southern blotting	Detection
Northern blotting	Detection
Heteroduplex migration assay (CSGE)	Scanning
Single-strand conformation polymorphism analysis (SSCP, SSCA)	Scanning
Denaturing gradient gel electrophoresis (DGGE)	Scanning
Temperature-gradient electrophoresis (TGGE and TGCE)	Scanning
DNA sequencing	Detection
Single-nucleotide extension assay (SNE)	Detection
Oligo-ligation assay (OLA)	Detection

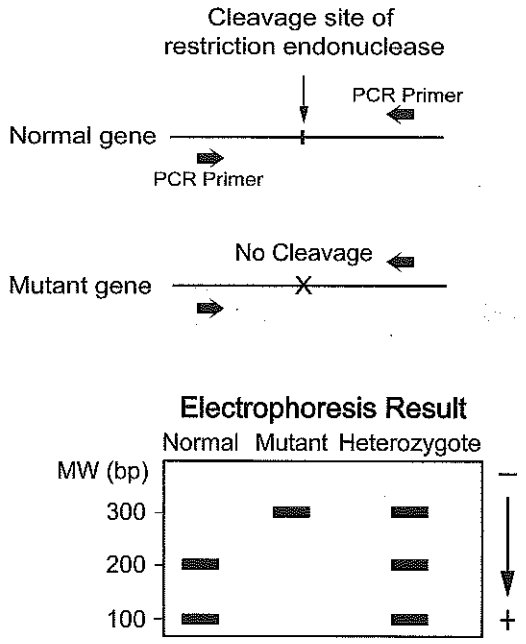

Figure 37-8 An example of PCR-RFLP. A DNA fragment amplified by PCR carries a site (a unique sequence of generally four or more bases) that is recognized and cleaved by a restriction endonuclease. If the mutation is present, this site is altered and is no longer recognized by the enzyme. Electrophoresis reveals that the fragment from a normal specimen was indeed cut by the enzyme, generating two fragments shorter than the original length, while the fragment from a homozygous mutant was not cut and the original length of the amplicon is preserved. In a heterozygous mutant, both the original fragment and the shorter fragments are visible.

not necessary in many of these assays. The length differences may be large and easily picked up with agarose gel electrophoresis or small enough to require a denaturing polyacrylamide matrix. Fluorescent labels may be incorporated into the product during the PCR to simplify detection of the fragment lengths. These techniques are most widely used in diagnosis of fragile X syndrome (See Chapter 40, Inherited Diseases) and in identity assessment (Chapter 41).

Direct analysis of PCR products by electrophoresis (without enzyme digestion) can also allow the final interpretation of an assay in which the presence of an amplification product is directly diagnostic (e.g., for the presence of a bacterium, virus, or fungus, in a specimen). The specificity of the amplification reaction is verified by the known size of the fragment. Internal negative and positive controls are employed to control for potential contamination and to establish detection sensitivity.

Direct PCR product analysis by electrophoresis is also frequently used in the clinical laboratory to query the quality of intermediary steps prior to the assay. (For example, was the nucleic acid isolated successfully? How well was it purified? Did the amplification work? How specific was the PCR? And so on).

Southern Blotting

When a DNA alteration spans a large region that is not easily amplified by PCR, Southern blotting (or Southern blot analysis) can be used to detect the alteration (Figure 37-9). The original sample DNA (rather than an amplified fragment) is digested by a restriction endonuclease, separated by agarose electrophoresis, and transferred to a solid support followed by selective visualization of fragments by hybridization of labeled probes. A nylon or nitrocellulose membrane

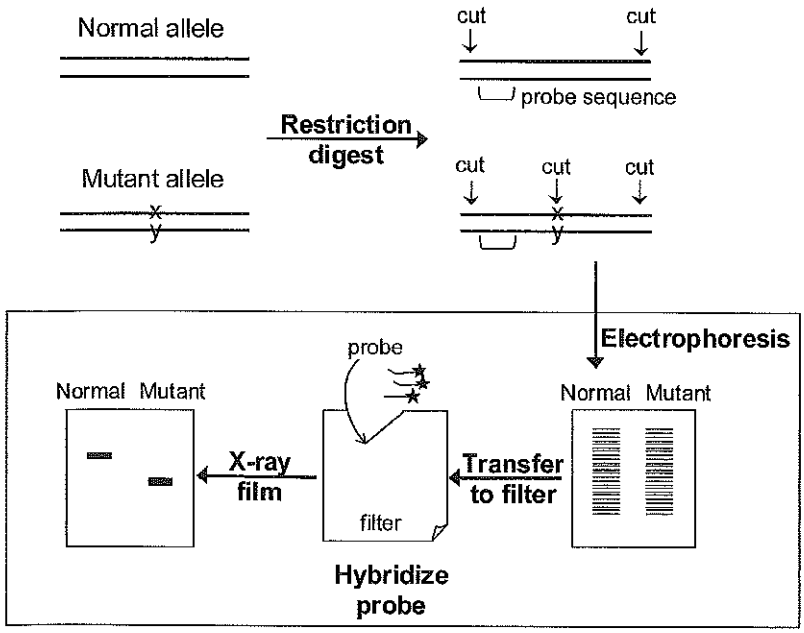

Figure 37-9 Schematic of Southern blotting. Genomic DNA is isolated from a normal specimen and from a mutant specimen carrying the polymorphic allele (x,y). The mutant allele generates a new site that is recognized by the enzyme. The normal specimen does not have this site. After restriction enzyme digestion of genomic DNA, both samples are separated by agarose electrophoresis. At this point, no discrete bands are visible over the background of many fragments that are generated by the enzyme. DNA is transferred to a filter and hybridized with a short DNA probe that is radioactively labeled. This probe hybridizes to the genomic sequence on one side of the polymorphic site. After exposing the filter to x-ray film, a smaller, digested band is seen in the specimen with the mutant allele compared with the larger fragment seen in the normal specimen.

(or filter) is usually used as the support. Details of the transfer process differ, but most methods use acid treatment to fragment the DNA (thus making it smaller and easier to elute from the gel), followed by base denaturation (single strands bind to membranes much more efficiently) and neutralization. Original methods of transfer relied on capillary action, with the filter placed in contact with the gel and absorbent paper stacked on top to blot the transfer buffer and DNA onto the filter. Typically, this process was allowed to proceed overnight. Vacuum or pressure systems can be used to speed the transfer. After transfer, DNA is permanently immobilized on the filter by baking or ultraviolet cross-linking. The filter is then incubated with a single-stranded probe that forms a stable complex with its complementary target affixed on the filter. If the original DNA was of good quality and if restriction enzyme treatment was complete, the fragments of interest can be visualized on film (autoradiographic or chemiluminescent) or directly on the filter (colorimetric) (see Figure 37-9). Ten to 50 µg of genomic DNA is usually sufficient for detection. The procedure was named after its inventor, E. M. Southern.[92] Southern blot analysis reveals polymorphisms in the DNA sequence based on the RFLP profile made visible by probes. It can also detect large structural alterations, such as deletions, duplications, insertions, and rearrangements. Southern blotting is labor-intensive and takes much longer than PCR.

Northern Blotting

Northern blotting was not named for its inventor, but as a companion technique that uses RNA rather than DNA as the test nucleic acid. RNA is transferred from the gel after electrophoresis onto a solid support followed by hybridization with a specific labeled probe. Because RNA molecules have defined lengths and are much shorter than genomic DNA, it is not necessary to cleave RNA before electrophoresis. However, because of the secondary structure of RNA, it is necessary to perform electrophoresis under denaturing conditions, usually formaldehyde/formamide buffers in agarose gels. RNA extracted from cells consists primarily of ribosomal and transfer RNA. Messenger RNA comprises only 1% to 2% of total cellular RNA. After electrophoresis and staining, undegraded RNA reveals two clearly visible bands of ribosomal RNA. Electrophoresis of about 10 µg of RNA is usually sufficient to see the mRNA of interest after hybridization with a probe. Northern blotting provides information about the size of mRNA transcripts. While only semiquantitative, the relative concentration of a particular transcript can be estimated by reference to a constitutively expressed control transcript, such as actin.

Heteroduplex Migration Analysis

Heteroduplex migration analysis (also called conformation-sensitive gel electrophoresis, CSGE) reveals the presence of mutations by the altered electrophoretic mobility of a double-stranded DNA fragment that contains one or more mismatched bases (a heteroduplex) versus one that is perfectly matched (a homoduplex). Originally described as a PCR artifact,[66] heteroduplex migration analysis has become a popular mutation-scanning technique, primarily because of its technical simplicity. Double-stranded DNA generated by PCR is denatured, then allowed to reanneal, and electrophoresed under slightly denaturing conditions (e.g., 15% urea, 40 °C) on polyacrylamide gels (often with special gel preparations that are available for this application). Detection is performed by silver staining of the gel, or by fluorescence detection if one of the PCR primers is labeled. Heteroduplexes usually tend to migrate more slowly than homoduplexes during electrophoresis (Figure 37-10). While mutant alleles are often present as heterozygotes in a clinical specimen, homozygous mutations require mixing with wild-type DNA for the mutations to be detected.

The ability of this technique to detect polymorphisms is relatively good, and the presence of a single nucleotide polymorphism in a fragment as large as 600 bp can be detected.

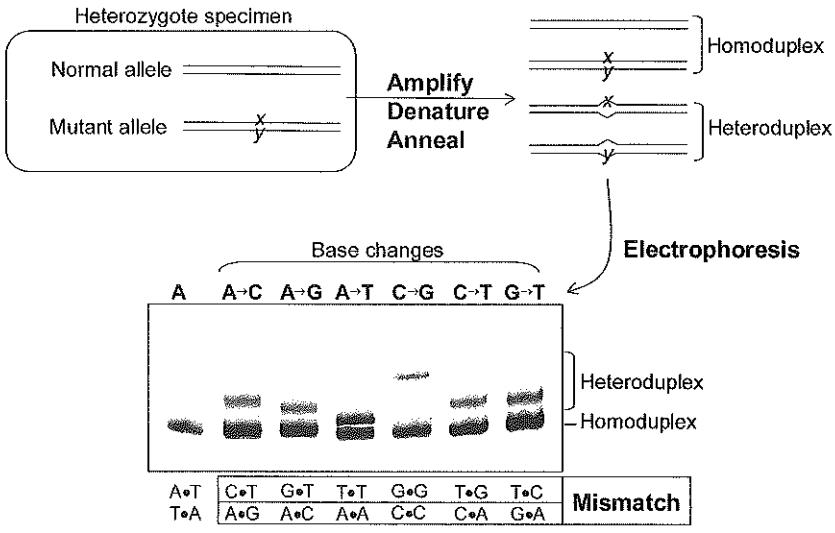

Figure 37-10 A schematic of heteroduplex migration analysis. When amplified DNA from a heterozygous specimen is denatured and cooled, the fragments reanneal in four combinations. Electrophoresis on a specialized polyacrylamide gel reveals the presence of heteroduplexes by extra band(s) appearing above the homoduplex band.

The principal factor influencing the sensitivity of this technique to base changes is the combination of the mismatched bases. Greater mobility differences (relative to the homoduplex) occur in the order of G:G/C:C > A:C/T:G = A:G/T:C > A:A/T:T.[34] This and other mutation-scanning methods are useful when a wide variety of sequence alterations might be present. Particularly when most of the samples tested are wild-type ("normal"), it is more economical to scan for the presence of mutations before performing specific genotyping or DNA sequence analysis.

Single-Strand Conformation Polymorphism Analysis

Single-strand conformation polymorphism analysis (SSCP, or SSCA) is another electrophoresis technique used to scan for unknown variants in nucleic acid sequence. Similar to heteroduplex analysis, it first requires PCR amplification. The amplicon is then diluted, denatured with heat and formamide, and the resulting single-stranded DNA is separated by nondenaturing polyacrylamide electrophoresis (usually run at 4 °C). During electrophoresis, the single-stranded molecules fold into three-dimensional structures according to their primary sequence. Electrophoretic mobility then becomes a function of size and shape of the folded single-stranded molecules. If the sequence of a reference sample differs from that of the fragment being tested, even by only a single nucleotide, it is possible that at least one of the strands, if not both, will adopt different conformations and exhibit a unique banding pattern (Figure 37-11). Since its introduction in 1989,[73] SSCP has emerged as one of the most popular mutation-detection strategies. Results can be visualized by silver staining of the gel or by fluorescent detection using labeled primers during PCR. Unlike heteroduplex migration analysis, there is no need to mix reference materials to detect the presence of a homozygous mutant specimen. Reports on the sensitivity of the SSCP technique have been variable, and detection rates seem influenced by the G + C content of the fragment and the assay conditions.[35] Different conditions may be required to detect all mutations, making multiple runs sometimes necessary for one target sequence. Furthermore the results of SSCP are difficult to interpret when one sequence gives rise to multiple single-stranded conformations, some of which may be difficult to see, depending on the amplification and electrophoresis conditions. It is also difficult to establish reliable protocols for fragments greater than ~200 bp.

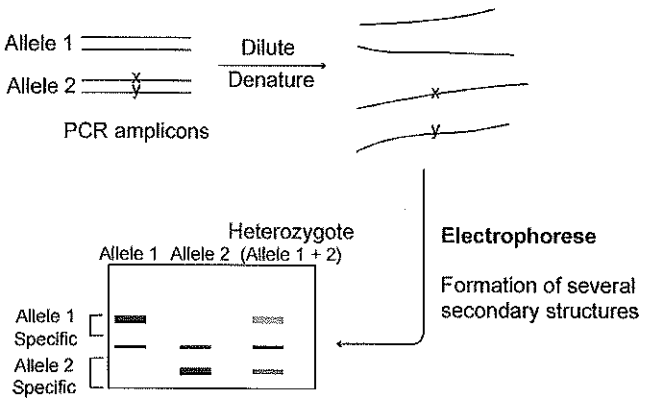

Figure 37-11 A schematic of single-strand conformation polymorphism analysis (SSCP). PCR amplicons carrying the polymorphic site (shown as x and y) are diluted and then denatured to form single-stranded fragments. When the fragments are electrophoresed, they assume secondary structures. When conditions are right, polymorphisms are detected by differential band patterns compared with a known sample.

Denaturing Gradient Gel Electrophoresis

Denaturing gradient gel electrophoresis (DGGE) is yet another technique to scan for unknown variants in nucleic acid sequence. Separation of a PCR product is performed at a constant temperature with a gel that includes a concentration gradient of denaturants, such as urea, along the direction of electrophoresis. If the sequence of the PCR product is known, the detection rate of mutations can reach 100%. However, creating identical gels is challenging, making routine implementation difficult. Depending on the melting characteristics of the product, it may be necessary to attach an artificial GC-rich sequence *(GC clamp)* to one end of the fragment to provide optimum separation.[15]

Temperature-Gradient Electrophoresis

Temperature gradient electrophoresis is an analog of DGGE. Instead of using denaturants, a spatial or temporal temperature gradient is used to provide the denaturing effect. Initial designs placed an electrophoresis gel over an insulated metal plate with a linear temperature gradient established perpendicular or parallel to the direction of electrophoresis (temperature gradient gel electrophoresis, or TGGE).[82] Separation occurs according to size, shape, and thermal stability of the nucleic acids. If the temperature gradient is established perpendicular to the direction of electrophoresis, intramolecular conformational changes show up as continuous transition curves, while strand-separation leads to discontinuous transitions. Heteroduplexes are detected by a shift of the transition curves to lower temperatures.

Temperature gradients can also be applied during capillary electrophoresis.[55] A portion of the capillary array is placed inside a heating chamber whose temperature is computer controlled to generate a gradual heat ramp (typically a 10 °C ramp at 0.5 °C to ~0.7 °C/min). Similar to the heteroduplex migration assay, PCR products are first denatured, reannealed, and then injected into the capillary. The electrophoresis polymer solution contains an intercalating dye and nucleic acids are detected by fluorescence. The presence of a heteroduplex is detected by a change in the peak profile, which under certain conditions may show all four possible duplexes as peaks[26] (Figure 37-12). The sensitivity of this technique for detecting the presence of het-

eroduplexes is very good, and many samples can be run at once. However, as with heteroduplex migration analysis, a homozygous mutant sample is difficult to discriminate from a homozygous normal sample without mixing the two together to form heteroduplexes.

DNA Sequencing

DNA sequencing,[24] once strictly a research technique, is now routinely performed in the clinical laboratory. The actual nucleic acid sequence of a DNA fragment can be determined and compared with a reference sequence with an error rate of 0.1% (one misidentified base in 1000). Often the sequence is analyzed on both strands (sense and antisense), which will provide even greater accuracy. Any deviation from the reference sequence is identified using computer programs matching the sequences. Base changes resulting in an altered amino acid code, stop codons, deletions, or insertions can be identified. The most common sequencing strategy uses PCR in the first step to amplify the region of interest, followed by a variation of the chain-termination reaction developed by F. Sanger in the late 1970s.[86] This reaction (also referred to as the Sanger reaction) generates fragments that are terminated at various lengths by the incorporation of one of the four dideoxynucleotide base analogs (Figure 37-13) during extension from the sequencing primer (Figure 37-14). Dideoxynucleotides lack the 3′ hydroxyl group (OH) and the 2′OH on the pentose ring, and because DNA chain growth requires the addition of deoxynucleotides to the 3′OH group, incorporation of this base analog terminates chain growth. The most common method for generating these terminated fragments is *cycle sequencing*, repeating the steps of annealing, chain extension and termination, and denaturation by temperature cycling, similar to PCR. The fragments generated are tagged with a fluorescent dye (by use of either labeled primers or labeled terminator dideoxynucleotides), then separated by denaturing polyacrylamide gel or capillary electrophoresis, and detected by fluorescence detection as the fragments travel past the detector (Figure 37-15). When fluorescently labeled primers are used, four tubes are needed for separate termination reactions. If only one color is used, then each termination reaction mixture is electrophoresed in a separate lane or capillary. If four colors are used, then the termination reactions can be combined before electrophoresis and only one capillary is necessary. Alternatively, the use of four terminators of different colors makes it possible to streamline the process down to one tube for the termination reactions and one capillary. About 600 bases can be resolved in a 2½-hour run on a capillary electrophoresis instrument. DNA sequencing is most commonly used in infectious disease testing, such as genotyping of HIV for drug resistance and of HCV to establish prognosis and appropriate therapy. Whole-gene sequencing for the detection of disease-causing mutations is still an expensive proposition, whether it is for population screening (in which the majority of samples will not have a mutation) or even for patients affected with the disease. Therefore, in genetic testing, DNA sequencing is often performed only after an initial *mutation scanning assay* has determined the exons that need to be sequenced or otherwise genotyped.

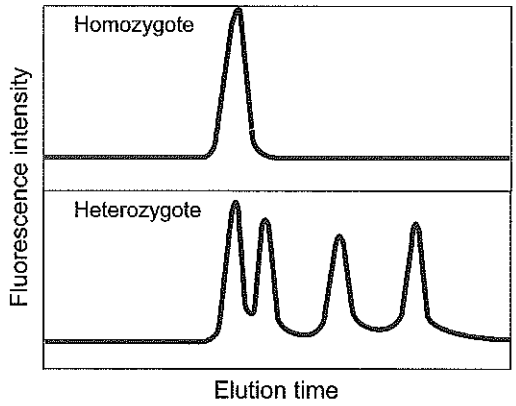

Figure 37-12 An example of temperature-gradient capillary electrophoresis (TGCE). The PCR fragments are denatured and annealed before the electrophoresis (see diagram in Figure 37-10). Only one peak is visible for the PCR fragment of a normal homozygous specimen, whereas all four possible duplexes are visible and separated from each other in a heterozygous mutant specimen. The shape of the elution profile (rather than the elution time) is used to compare unknowns with control samples.

Single Nucleotide Extension Assay

Also known as *single-base primer extension* or *minisequencing*, single nucleotide extension (SNE) assays involve the

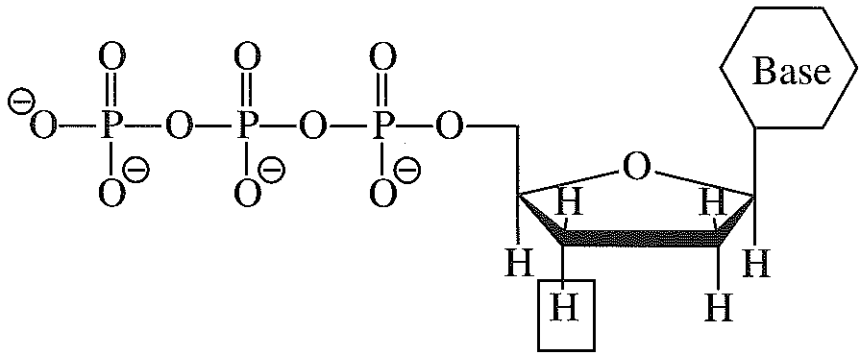

Figure 37-13 A dideoxynucleotide. Notice the absence of the 3′-OH that is usually present in standard deoxynucleotides.

annealing of an oligonucleotide primer to a single-stranded PCR amplicon at a location that is immediately adjacent to, but does not include, the site of the SNP, followed by enzymatic extension of the primer in the presence of polymerase and dideoxynucleotide terminators without dNTPs. Each of the four terminators is labeled with a unique label so that it is possible to detect which base was incorporated. SNE assays can be multiplexed on automated DNA sequencing instruments by varying the lengths of the primers so that each SNP is resolved by size in one electrophoresis run. There are also many nonelectrophoresis methods to read out the results of an SNE assay, including colorimetric detection on microtiter plates, product-capture detection systems on DNA microarrays, bead hybridization assays detected by flow cytometry, solution-based fluorescence polarization detection systems, and mass spectrometry. SNE assays are useful when the gene of interest contains a relatively large number of disease-causing SNPs. SNE assays do not work well if there are polymorphisms in the primer-binding site. Nor will they detect polymorphisms at a position other than immediately adjacent to the 3′ end of the primer.

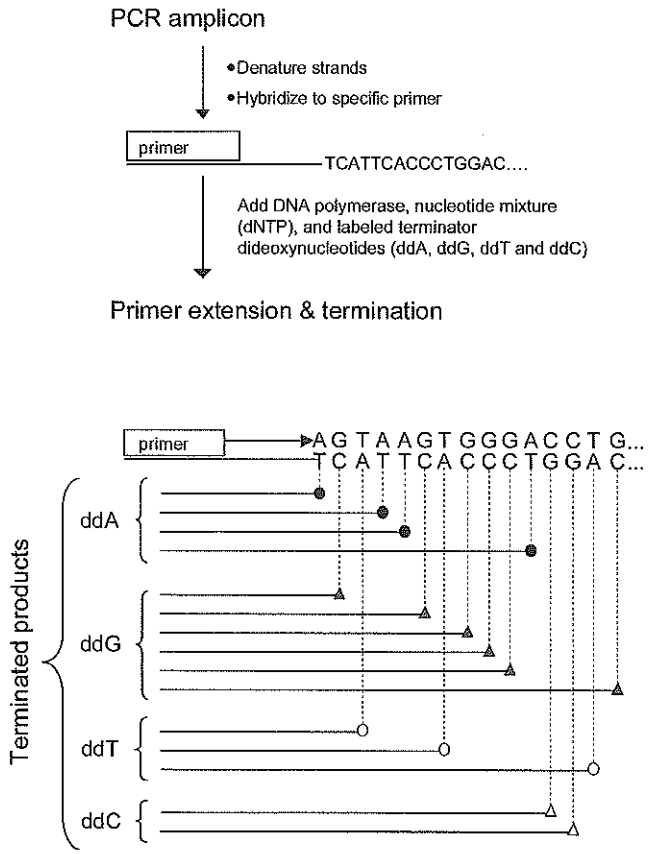

Figure 37-14 The chain-termination reaction (Sanger). A PCR amplicon is denatured and then hybridized to a specific oligonucleotide primer. As the DNA polymerase extends the primer by incorporating bases (dNTPs) complementary to the template, it occasionally incorporates a terminator base analog (ddA, ddG, ddT, or ddC) that stops further extension. The result is a mixture of extended products with varying lengths. Each terminator base may be labeled with one of four different fluorescent tags (shown as different symbols in the diagram). Alternatively, the primer can carry four different fluorescent tags in individual chain-termination reactions (containing only one ddNTP) performed in separate tubes. The original procedure incorporated a radioactive dNTP during extension, allowing monochromatic detection of the truncated fragments that were electrophoresed in four separate lanes, each for one of the terminator bases (see Figure 37-15).

Oligo Ligation Assay

Another assay format frequently used in the clinical laboratory for SNP detection is the oligo ligation assay (OLA). Two oligonucleotide probes are hybridized to adjacent sequences of amplified target DNA, with the known SNP site positioned at the end of one probe (Figure 37-16). DNA ligase covalently joins the two probes only if both probes are perfectly hybridized to the target including the polymorphic base. A probe matching the normal base and another probe matching the mutant base are usually prepared. These two can be discriminated by differential electrophoretic mobility by varying the number of modifying tail units attached. These tails were initially noncomplementary poly A or poly C tails but now consist of pentaethylene oxide (PEO) units. The probe hybridizing to both alleles (the *common probe*) provides the reporter molecule, usually a fluorescent label. Multiplexing of SNP detection is achieved by attaching different fluorescent labels to the common probes and also varying the numbers of tail units on the allele-specific probes. Following ligation, probes for multiple SNP sites are separated by denaturing polyacrylamide electrophoresis in the presence of labeled size standards.

Alternatives to Electrophoresis

Newer technologies that replace assays traditionally performed by electrophoresis are emerging, some of which are attractive alternatives for the clinical laboratory as they achieve analysis of nucleic acids with less hands-on time and with far greater throughput because of automation. These include pyrosequencing, mass spectrometry, and HPLC.

Pyrosequencing

Pyrosequencing[84] is a method to determine the nucleic acid sequence of short segments without the use of electrophoresis. A sequencing primer is hybridized to a single-stranded template that is usually generated by PCR. Four enzymes, a DNA polymerase, ATP sulfurylase, luciferase and apyrase, and two substrates—adenosine 5′ phosphosulfate and luciferin—are included in the reaction mixture (Figure 37-17). One of the four dNTPs is added to the reaction (dATPαS is substituted for dATP because it is incorporated by the polymerase but is not a luciferase substrate). If the base is complementary to the template strand, DNA polymerase catalyzes its incorporation. Each incorporation event is accompanied by release of a pyrophosphate (PPi) so that the quantity of PPi produced is equimolar to the

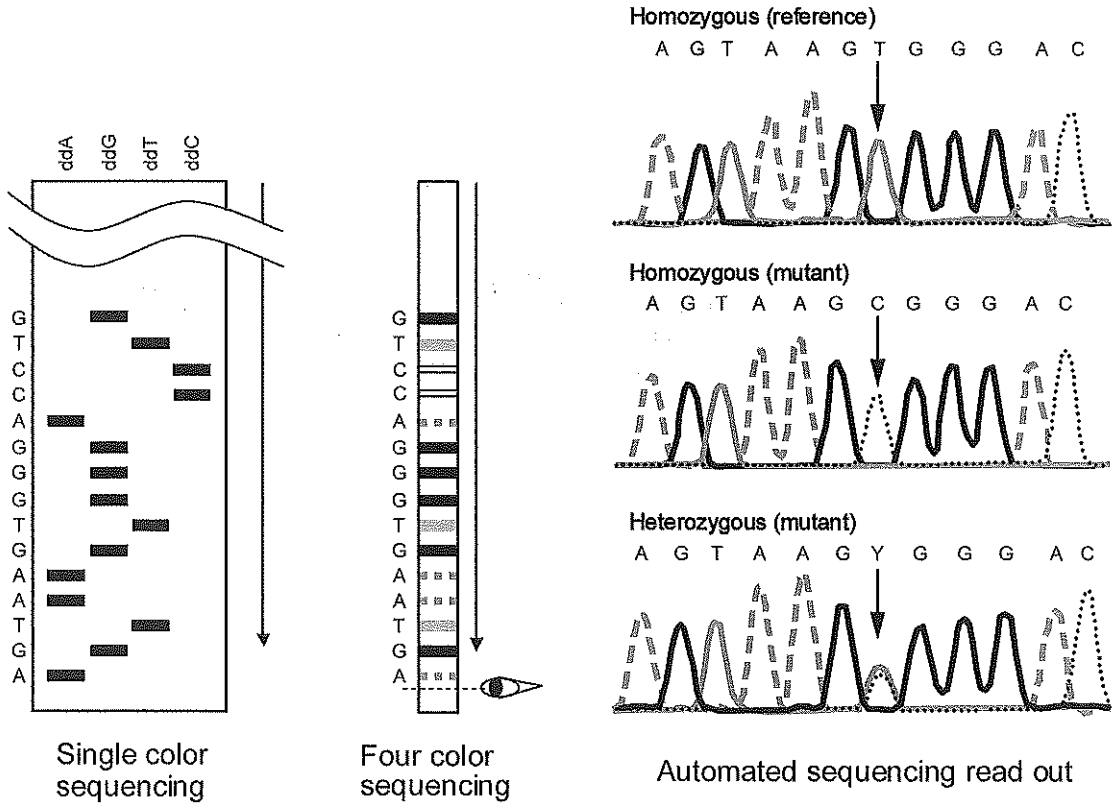

Figure 37-15 Schematic of DNA sequencing. Extension products generated by the chain-termination (Sanger) reaction are separated using four lanes (if only one label is used), or using one lane (if different color dyes are used for each of the terminator reactions). The four-color strategy is amenable to automated end-point fluorescence detection (shown by the eye icon) for both slab gel and capillary electrophoresis. The direction of fragment migration is from top to bottom. Sequence read is from bottom to top in the gels, and from left to right for the automated sequence. Examples of a reference sample (homozygous T at the polymorphic site), a mutant sample (homozygous C), and a heterozygous mutant sample (T and C) are shown.

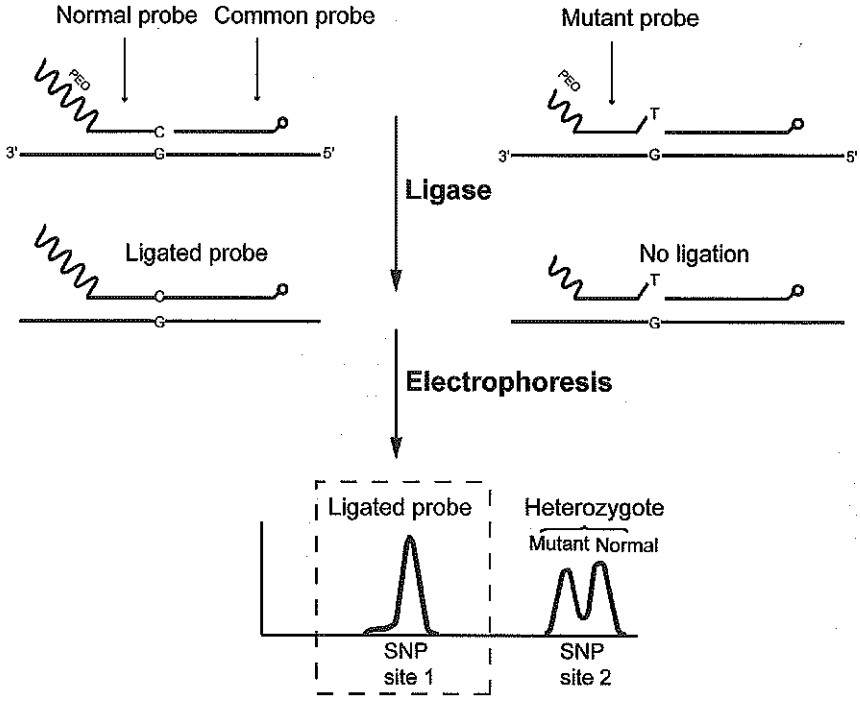

Figure 37-16 Oligo ligation assay. A probe specific to the normal allele (C) is shown hybridized onto a normal DNA sample (G). This probe also is attached to a mobility modifying tail (PEO). Hybridized next to the normal-allele probe is the common probe that is labeled with a fluorescent tag. In the presence of ligase, the two probes are covalently joined to generate a longer probe. The mutant-allele specific probe (T) with a shorter PEO tail also hybridizes to the normal DNA sample but is not ligated to the common probe because of the mismatched base at its 3′ end. Electrophoresis and end-point, laser-induced detection reveals the ligated normal-allele probe, which can be differentiated from the significantly shorter common probe alone (not shown on the graph) or from a ligated mutant-allele probe because of the different lengths of PEO tails. Multiple SNP sites can be analyzed in one electrophoresis assay by varying the tail lengths (e.g., SNP site 2 in graph), or by use of multicolor fluorescence tags.

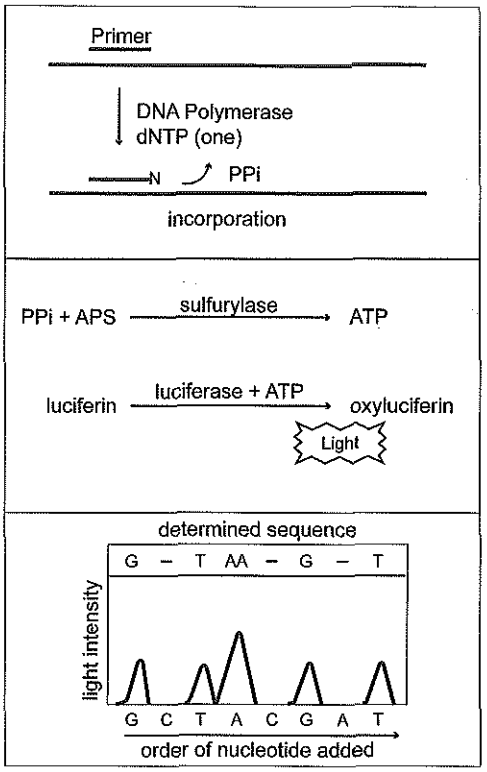

Figure 37-17 Schematic of pyrosequencing. Individual dTNPs are added one by one to the single-stranded template, a primer, and a polymerase. Pyrophosphate is generated if the dNTP is complementary to the next base on the template *(top)*. Any pyrophosphate produced reacts with adenosine-5′-phosphosulfate (APS) to produce ATP, which in turn generates light in the presence of luciferase *(middle)*. The sequence can be determined from the order of dTNP addition and the intensity of light produced.

amount of incorporated nucleotide. The release of PPi is monitored by conversion of PPi and adenosine 5′ phosphosulfate into ATP by the ATP sulfurylase, and ATP in turn drives conversion of luciferin into oxyluciferin, which generates visible light. The light produced is proportional to the number of nucleotides incorporated. Apyrase, which is a nucleotide-degrading enzyme, continuously degrades ATP and unincorporated dNTP. This switches off the light in preparation for the next dNTP addition. As the process is repeated by adding one dNTP at a time, the complementary DNA strand is built and the nucleotide sequence is determined (see Figure 37-17). Because the technique can be automated, it is useful when the sequences of a large number of short segments need to be determined.

Mass Spectrometry

Matrix-assisted laser-desorption ionization time-of-flight (MALDI-TOF) mass spectrometry can be used to detect sequence polymorphisms.[14,79] With mass spectroscopy, no label is necessary because the alleles differ in mass. After isolation of genomic DNA, a specific DNA fragment including the polymorphic site is amplified by PCR. Heat-labile alkaline phosphatase is added to the reaction to dephosphorylate any residual nucleotides, preventing future incorporation and interference with the primer extension assay. Samples are then heated to inactivate the alkaline phosphatase. An extension primer is hybridized directly or closely adjacent to the polymorphic site. Appropriate unlabeled deoxynucleotides and/or dideoxynucleotides are incorporated through the polymorphic site and terminated with the incorporation of a dideoxynucleotide generating allele-specific diagnostic product of different mass. Salt is removed from the sample, and ~10 nL of it is spotted onto an array coated with 3-hydroxypicolinic acid. This is placed into the MALDI-TOF, which measures the mass of the extension products. Once the mass is determined, the genotype is determined (Figure 37-18). Despite its complexity, automated systems processing 384 to 1536 samples at once are available.

High-Performance Liquid Chromatography

HPLC is commonly used for separating and purifying oligonucleotides. Separation is usually based on ion-pair, reversed-phase chromatography and is particularly useful for purifying fluorescently labeled probes guided by absorbance and fluorescent elution profiles.

A more recent variant of this technology is denaturing HPLC (dHPLC). Denaturing HPLC is run at a single elevated temperature to partially denature double-stranded DNA. Similar to heteroduplex migration analysis, dHPLC analyzes a mixture of PCR amplicons that are denatured and reannealed, revealing the presence of heteroduplexes as additional peaks that are shifted in retention compared with the homoduplex sample.[113] To separate double-stranded DNA, alkylated nonporous poly (styrene-divinylbenzene) resins are used, with a hydroorganic eluent containing an amphiphilic ion (e.g., triethylammonium ion) and a small hydrophilic counter-ion (e.g., acetate). Retention of double-stranded DNA is governed by electrostatic interactions between the positive triethylammonium ions adsorbed to the resin and the negative phosphodiester groups of DNA. An increase in the concentration of organic solvent (e.g., acetonitrile) in the mobile phase results in desorption of the amphiphilic ions and the double-stranded DNA. UV is often used for detection; thus PCR amplicons do not have to be labeled. The system can also be connected to a multicolor laser–induced fluorescence scanner or a mass spectrometer. The limitations of dHPLC include the need to establish specific temperatures for distinct types of mismatches and that samples must be run sequentially, one at a time.

Hybridization Assays—Principles

The second major category of nucleic acid discrimination techniques is *hybridization*. All hybridization assays are based on the ability of single-stranded nucleic acids to form specific double-stranded hybrids. The process requires (1)

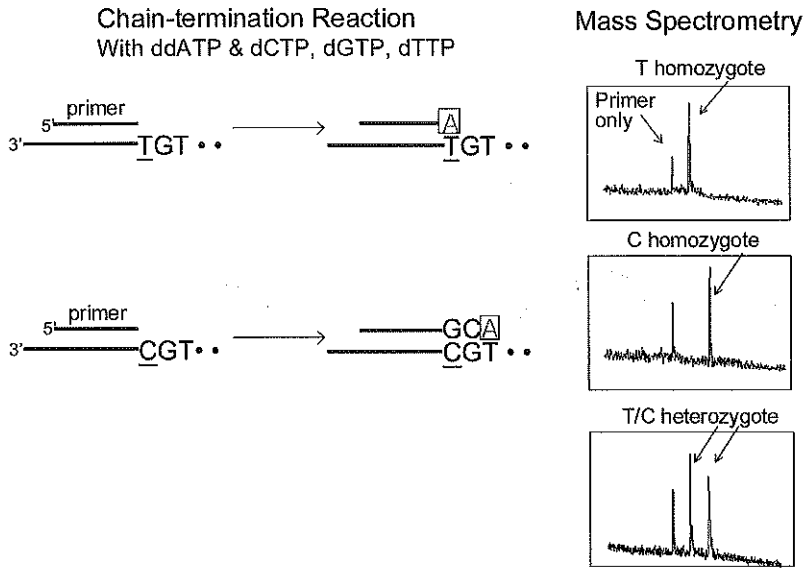

Figure 37-18 Sequence polymorphism analysis by mass spectrometry. The *underlined* base is the polymorphic site in the template (T or C). Single-stranded template is primed and extended in the presence of three dNTPs and one ddNTP, producing fragments of different mass depending on the sequence. The boxed "A" in this example indicates the incorporated terminator adenine base. The mass of terminated products is precisely measured by MALDI-TOF mass spectrometric data (relative intensity versus m/z).

that probe and target nucleic acids are mixed under conditions that allow for specific complementary base pairing and (2) that there is a method to detect any resulting double-stranded nucleic acids. A *probe* indicates a nucleic acid whose identity is known, and the *target* or *sample* is a nucleic acid whose identity or abundance is revealed by hybridization. In some of the methods discussed here, hybridization occurs between a target in solution and a probe that is tethered to a solid surface. In *homogeneous* or *real-time* techniques, both the probes and the targets are in solution, and hybridization and detection occur without washing steps. Some of the homogeneous methods also monitor the dissociation of hybridized duplexes under controlled heating, revealing the identities of the hybridized duplexes by *melting curve* signatures.

As with any assay, both positive and negative controls are necessary for validation of hybridization assays. A positive control is one known to contain sequences complementary to the probe. They are used to establish that sample preparation is adequate to release target for the assay and to ensure that the probe will hybridize to the target under the assay conditions. The positive control may also be used to monitor the detection limit of the assay if it is chosen near the lower limit of detection. A negative control (i.e., one known not to contain sequences complementary to the probe) is used to monitor specificity of the probe-target interactions, and to detect the presence of positive contamination if any is present. Negative controls also allow monitoring of the background signal generated.

Hybridization Thermodynamics

The thermodynamically favored structure of DNA under physiological conditions is an ordered double-stranded helix formed of two separate DNA molecules held together by noncovalent interactions. The duplex structure is most stable when all opposing bases are complementary, allowing

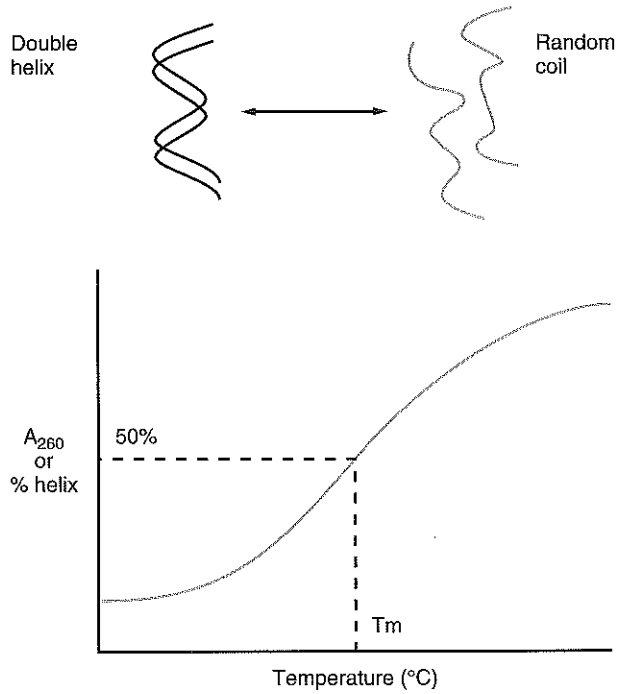

Figure 37-19 Melting curve of double-helical nucleic acid. *(Modified with permission from Piper MA, Unger ER: Nucleic Acid Probes: A Primer for Pathologists. Chicago, ASCP Press, 1989.)*

for maximal hydrogen bonding and base stacking. The noncovalent binding between two DNA strands is both specific (i.e., sequence-dependent) and reversible. Denaturing agents (such as high temperature [>90 °C], formamide, or extremes of pH) favor dissociation of the double-stranded molecule into two separate random coils (see Figure 37-19). On removal of the denaturant, single strands attempt to rejoin to re-form duplexes, strongly favoring interactions that maximize complementary base pairing. Because tempera-

ture is the denaturant most easily manipulated, double- to single-strand transformation is referred to as *melting*, and the temperature at which one half of the DNA is melted is referred to as the *melting temperature*, or *Tm*, of the duplex. Duplexes with mismatched base pairs are less stable than those with a perfect sequence match and thus melt at a lower temperature. The reverse process, in which two complementary strands recombine to form a stable duplex molecule, is referred to as *annealing* or *hybridization*. Hybridization can occur between DNA strands, RNA strands, and strands of nucleic acid analogs (such as peptide nucleic acids, also known as PNA[70]), in all combinations.

Stringency and Mismatches

The conditions of the hybridization reaction define the degree of base pair mismatch that will be tolerated in a duplex structure. The tolerance (or lack thereof) for mistakes in base pairing is referred to as the *stringency* of the hybridization reaction. Conditions of high stringency (low salt concentration, high formamide level, and high temperature) require exact base pairing. As the stringency of the hybridization assay is lowered (by increasing salt concentrations, lowering formamide level, and lowering temperature), increasing numbers of base pair mismatches are tolerated in a duplex structure. The stringency of the hybridization reaction is determined by the environment during the hybridization reaction and the subsequent washing steps designed to remove nonspecifically interacting nucleic acid.

Conventional hybridizations were performed in the presence of empirically determined ingredients selected to modulate the stringency of the reaction and to favor interaction of nucleic acid molecules through specific base pair hydrogen bonds rather than charge interactions. The components varied widely but included buffers, salts, denaturants such as formamide, high-molecular-weight polymers, carrier DNA or RNA, and various "magic" ingredients designed to reduce background (such as detergents, bovine serum albumin, skim milk, and ficoll). Such a complex mixture was conveniently referred to as a hybridization *cocktail*. The ionic strength was often determined by the concentration of a "saline sodium citrate" (SSC) buffer with a standard 1 × concentration of 0.15 mol/L NaCl and 0.015 mol/L sodium citrate (pH 7.0). In contemporary real-time PCR and melting analysis, the hybridization solution is the buffer in which PCR occurs, and there are no separate washing steps.

Hybridization Kinetics

The kinetics of solution-phase hybridizations are second order, being proportional to the concentrations of both hybridizing strands.[103] The rate-limiting step is nucleation, where a small number of base pairs are formed in the correct orientation, followed by a rapid "zippering" of complementary sequences. In the case of a probe present in great excess to the target, hybridization proceeds as a pseudofirst order reaction, depending only on the concentration of the target. However, the time required to hybridize the probe to a given fraction of the target remains proportional to the probe concentration. For example, during PCR the concentration of primers is much greater than that of the target, and the reaction rate during each annealing step depends on the concentration of available single-stranded product, but the time required to anneal primers to a certain fraction of the target is proportional to the primer concentration.

The availability of nucleic acids for hybridization can also be an issue. In PCR, primer annealing competes with the formation of double-stranded product. As the concentration of product increases during PCR, some double-stranded product is formed before primer annealing can occur (see Figure 37-4). Similarly, when double-stranded probes are used at high concentrations, probe self-annealing interferes with probe-target hybridization. Available hybridization sites can also be limited by intramolecular secondary structure of the probe or target (e.g., as seen in SSCP).

In addition to probe concentration and availability, the length of the probe and the complexity of the nucleic acids affect hybridization rates. Rates are directly proportional to the square root of the probe length and inversely proportional to complexity, defined as the total number of base pairs present in nonrepeating sequences. Mismatches up to about 10% have little effect on hybridization rates.

The rate of the hybridization reaction is influenced by many factors in the reaction environment, most notably temperature and ionic strength. Above the Tm, no stable hybrids are present, although transient complexes may form. As the temperature is lowered below the Tm, hybridization rates increase until a broad maximum occurs about 20 °C to 25 °C below the Tm. Hybridization rates also increase with the ionic strength. Divalent cations like Mg^{++} have a much stronger effect than monovalent cations like Na^{+} or K^{+}.

When the nucleic acid target or probe is immobilized on a solid support, the kinetics of hybridization are even more complex. Many of the preceding observations still hold true, but the rate and extent of solid-phase hybridization are lower than with solution-phase hybridization. Depending on the concentrations of the reactants, solid-phase hybridization can be either nucleation-limited or diffusion-limited. Optimal efficiency of solid-phase hybridization is achieved under conditions that facilitate diffusion of the probe to the support and that favor hybridization over strand-reassociation if double-stranded probes are used. This usually means a small volume of hybridization solution and relatively low probe concentrations. In practice, solid-phase hybridization assays are empirically designed. Time of hybridization and probe concentration are the two variables most frequently adjusted in the assay. Conditions that tend to maximize the extent of hybridization and minimize the background or nonspecific attachment of the probe are selected.

Probes

In a hybridization assay, the probe is analogous in its role and importance to the antibody in an immunoassay. As mentioned earlier, a probe is the nucleic acid whose identity

is known and is used to reveal the identity or abundance of a target or sample. Like antibodies in immunoassays, probes can be unlabeled or labeled with one of a variety of reporter molecules, depending on the technique used to detect hybridization. Probes may be cloned (recombinant), generated by PCR, or synthesized (oligonucleotides). They may be DNA, RNA, PNA, and single-stranded or double-stranded. Selection, purification, and labeling of probes are crucial to success of hybridization assays.

Cloned Probes

Cloned probes consist of a known segment of DNA inserted into a plasmid vector that is propagated by growth in a bacterium. Many different plasmid vectors are now available; pBR322 was one of the first in common use.[11] The probe may consist of the entire plasmid DNA (insert plus vector sequences), or the insert may be purified from the vector sequences. The latter method is obviously more cumbersome but may result in reduced background. The resulting probe is a double-stranded DNA probe and it must be denatured before use.

Some vectors contain RNA promoter regions adjacent to the inserted DNA sequence. These regions permit generation of RNA transcripts from the DNA insert. Because only one strand is copied during the RNA synthesis, single-stranded RNA probes are generated. Controlling the orientation of the insert in relation to the promoter region allows the production of transcripts in the "sense" direction (i.e., same as mRNA) or "antisense" direction (i.e., complementary to mRNA).

PCR-Generated Probes

PCR-generated probes are simple to prepare.[39] During amplification, the PCR product typically is labeled with nucleotides that are radioactive, are fluorescent, or have attached affinity labels. If desired, single-stranded probes can be obtained by using a biotin-labeled primer, followed by solid-phase separation with streptavidin.

Oligonucleotide Probes

Oligonucleotide probes are even easier to obtain than PCR-generated probes. These probes are usually 15 to 45 bases of single-stranded nucleic acid that are chemically synthesized to a specified base sequence. Most commonly, they are DNA, but RNA and PNA oligonucleotides can also be used. Automated, efficient, and accurate methods of synthesis continue to lower the cost of production. Sequence information is now routinely available in public databases (e.g., the NIH genetic sequence database, GenBank[8]) and a similarity check for probe sequence can be performed using public algorithms (e.g., BLAST). Probe sequences must be carefully chosen to minimize cross-hybridization with pseudogenes (eukaryotes) or related species (bacteria and viruses). The melting temperature of the probe should allow both favorable hybrid stability and discrimination between related sequences under the stringency of the assay. Oligonucleotide probes are often prepared with covalent attachment of a reporter molecule (such as fluorescent dyes) or affinity labels that allow them to be attached to solid supports. Probes used in homogeneous (real-time) PCR are usually oligonucleotides with a fluorescent label.

Estimating Tm of Oligonucleotide Probes

Significant recent progress in nearest neighbor stability calculations now allows probe Tm estimation to within 2 °C. A unified thermodynamic database has been compiled,[87] and new parameters for all possible single mismatches[1-4,76] and dangling ends have been estimated.[12] Many software programs and Web sites are available for in silico Tm estimation.

Purity of Labeled Oligonucleotide Probes

The purity of labeled oligonucleotide probes is an important factor for success in hybridization assays and critical in homogeneous PCR assays. Commercial oligonucleotides with a fluorescent label are of variable purity. End users are well advised to assess the concentration and purity of all fluorescently labeled probes before use. A good method is to first calculate the predicted absorbance coefficient (usually referred to in tables by the older term "extinction coefficient") of the oligonucleotide at 260 nm ($e_{260(oligo)}$) using nearest-neighbor absorbance values. These values have been tabulated[13] and are also used by many software programs to calculate the related value, nmol per absorbance unit at 260 nm, or $nmol/A_{260(oligo)}$, which can be converted into the extinction coefficient by the formula $e_{260(oligo)} = 10^6/(nmol/A_{260(oligo)})$. Next the concentration of the fluorescent label (C_{fluor}) can be calculated from the extinction coefficients provided in the literature or by the supplier

$$C_{fluor} = A_{\lambda max\ of\ fluor} / e_{\lambda max\ of\ fluor}$$

The concentration of the fluorescently labeled oligonucleotide is calculated as

$$C_{oligo} = [A_{260} - (A_{\lambda max\ of\ fluor} \times e_{260(fluor)} / e_{\lambda max\ of\ fluor})] / e_{260(oligo)}$$

This equation takes into account the A_{260} contribution from the fluorophore. Similar equations for more than one label can be derived. The concentrations of fluorophore and oligonucleotide should be nearly equal (i.e., the ratio of fluorophore to oligonucleotide should be near 1). Acceptable ratios are between 0.8 and 1.2. Ratios less than 0.8 suggest incomplete labeling or destruction of the attached dye. Ratios greater than 1.2 suggest the presence of free dye. A ratio near 1 is a necessary but not a sufficient criterion of a pure probe. Co-elution of the A_{260} peak and the fluorescence peak on reversed-phase HPLC is additional evidence of purity.

Hybridization Assays—Examples

Hybridization reactions can be divided into two broad categories: *solid-phase,* in which either probe or target is tethered

TABLE 37-3 Hybridization Assays

Solid-Phase Hybridization	• Dot-blot and line-probe assays • Arrays (microarrays and medium-density arrays) • In situ hybridization • Southern and Northern blotting (reviewed earlier)
Solution-Phase Hybridization	• Real-time (or homogeneous) PCR • PCR melting analysis • Other classical techniques

to a solid support while the other is in solution, and *solution-phase* hybridizations, in which both are in solution (Table 37-3). Somewhat surprisingly, nucleic acids bound on a solid matrix can still bind complementary nucleic acids. Solid-phase assays are useful because multiple samples can be processed together, facilitating control, washing, and separation procedures. Hybridization on a solid support is, however, less efficient than solution-hybridization and the kinetics are slower and more difficult to predict. Both solid-phase and liquid-phase assays are used routinely in the clinical laboratory. Solid-phase assays include dot blots, line probes, arrays, in situ hybridization, and Southern and Northern blotting.

Several classical hybridization methods used probe-target hybridization in solution, followed by either the removal of the unbound labeled probe (by exclusion chromatography or electrophoresis) or capture of the probe-target hybrid (by hydroxyapatite, magnetic particles, or other affinity capture methods). The signal from the labeled probe-target complex was then measured. For example, *hybrid capture* methods use a bound antibody that is specific for RNA-DNA hybrid molecules that are formed during solution-phase hybridization of a DNA sample and an unlabeled RNA probe. The assay can be adapted to a microtiter plate format for automation of washing and detection.

Recently, solution hybridization has been combined with amplification, detection, and quantification and analysis all in the same tube. These homogeneous, closed-tube, real-time assays do not require any additions, washing, or separation steps.

Dot-Blot and Line-Probe Assays

Conventional hybridization assays on membranes are known as dot blots or line probes, depending on the geometry of the individual spots. The nucleic acids are applied with suction, using a commercially available manifold that results in a shape that is either round (dot) or elongated (line or slot). After immobilization, the membrane is incubated with complementary nucleic acid at a constant temperature, followed by one or more washes to discriminate matched from mismatched nucleic acid. The method allows multiple probe-target hybridizations to be carried out simultaneously under identical conditions.

Two general formats are used for these assays: either multiple samples are affixed to the solid support and interrogated by a small number of probes ("sample-down"), or multiple probes are attached to the support and a small number of samples is used ("probe-down") (Figure 37-20). In the sample-down format, purified nucleic acid or amplified fragments from multiple samples are immobilized on the support.

In the probe-down format, unlabeled probes bound to the filter are allowed to interact directly with a specimen that carries the label (a technique also known as "reverse dot blot"). Alternatively, instead of having to label the sample, a set of secondary probes can be used for signal generation. Signal probes remain attached to the filter only through sample-mediated hybridization; the sample nucleic acid forms a sandwich between the immobilized probe and the signal-generating probe. Similar assays have been developed substituting microtiter plate wells for filters. This requires chemical modification of the plastic wells to bind short DNA probes at one end, allowing the bound probes to hybridize to sample, but this approach is more amenable to automation of washing and detection.

Results of a dot-blot or line-probe assay are usually qualitative: if hybridization has occurred, a signal is generated at the specified spot and a simple yes/no interpretation is given. As the number of probes or samples increases, it becomes challenging to find a hybridization condition that provides high stringency for all probe-target combinations.

Arrays

Extending further the concept of increasing the level of parallelism in hybridization assays, microarrays (also called DNA arrays or DNA chips) were introduced in the mid1990s.[88] Compared with dot-blot and line-probe assays, spot sizes in microarrays are decreased (typically to less than 200 microns in diameter) such that one array can contain thousands of spots. This dimensional change requires specialized detection equipment, software, and informatics to analyze the data. Microarrays are fabricated on solid surfaces (generally on glass, but sometimes on other supports, such as gel pads or coated gold surfaces) either by in situ synthesis of oligonucleotides or by physical spotting of probes with the aid of robotic arraying equipment or electronic addressing. (Hybridization arrays and fabrication of "chips" have been described in Chapter 10 and will not be further described here.) Because of its massively parallel capability, microarrays have attracted tremendous interest among researchers who wish to monitor the whole genome (or at least a significant portion of the genome) for (1) identification of sequence polymorphisms and mutations and (2) quantification of gene expression. The development of expressed-sequence-tag (EST) clone libraries has greatly contributed to the advancement of gene expression microarrays. ESTs are short sequences that are expressed in certain

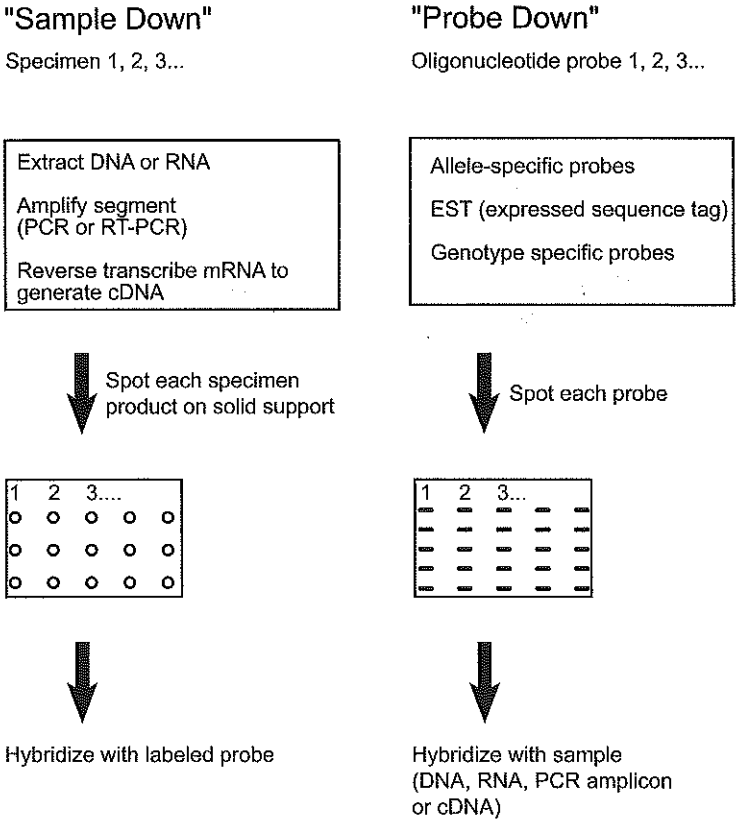

Figure 37-20 Two modes of dot-blot and line-probe assays. In the "sample-down" mode, DNA, cDNA, RNA, or amplified products are attached to the solid support and hybridized to labeled probes in solution. Alternatively, different probes are spotted onto the support ("probe-down") and the sample is in solution.

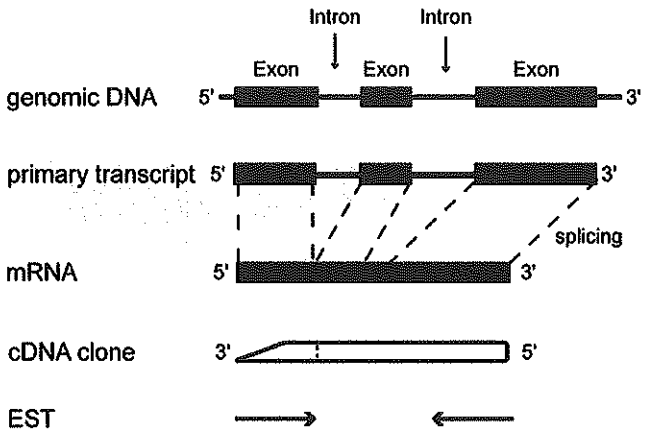

Figure 37-21 Expressed sequence tags (ESTs) can be used as probes to identify expressed genes by hybridizing to mRNA or cDNA.

cells, tissues, or organs at different developmental stages (Figure 37-21). An example of a two-color comparative EST microarray used in gene expression studies is shown in Figure 37-22. Studying gene expression in tumors can lead to the discovery of new diagnostic or prognostic markers and novel therapeutic targets. For example, characteristic patterns of gene expression can classify breast tumors into clinically relevant subgroups.[91] Expression microarrays have also identified specific signaling pathways in follicular lymphoma transformation, suggesting therapeutic targets.[23] The promise of microarrays is accompanied by challenges, including the need for strict requirements for controls and good experimental design.

Following the advent of high-density microarrays, arrays of lower density were introduced that still process more hybridization reactions than classical dot-blot or line-probe formats. Sometimes called *medium-density arrays,* these tools are emerging in the clinical laboratory for genetic disease, oncology, and pharmacogenetic testing of specimens for multiple mutations. Many companies are involved in the supply of microarray and medium-density array systems, and the industry is moving swiftly.[33,38] The arrays do not need to be attached to a two-dimensional surface as long as their "address" can be decoded. For example, microspheres can be coded by fluorescence intensity in two different channels, while fluorescence in a third channel monitors hybridization. All channels can be read simultaneously using a flow cytometer.[41] Some characteristics of arrays are listed in Table 37-4. A literature survey of array technology and applications has been published.[45]

In Situ Hybridization

In situ hybridization is a specialized type of solid-support assay in which morphologically intact tissue, cells, or chromosomes affixed to a glass microscope slide provide the

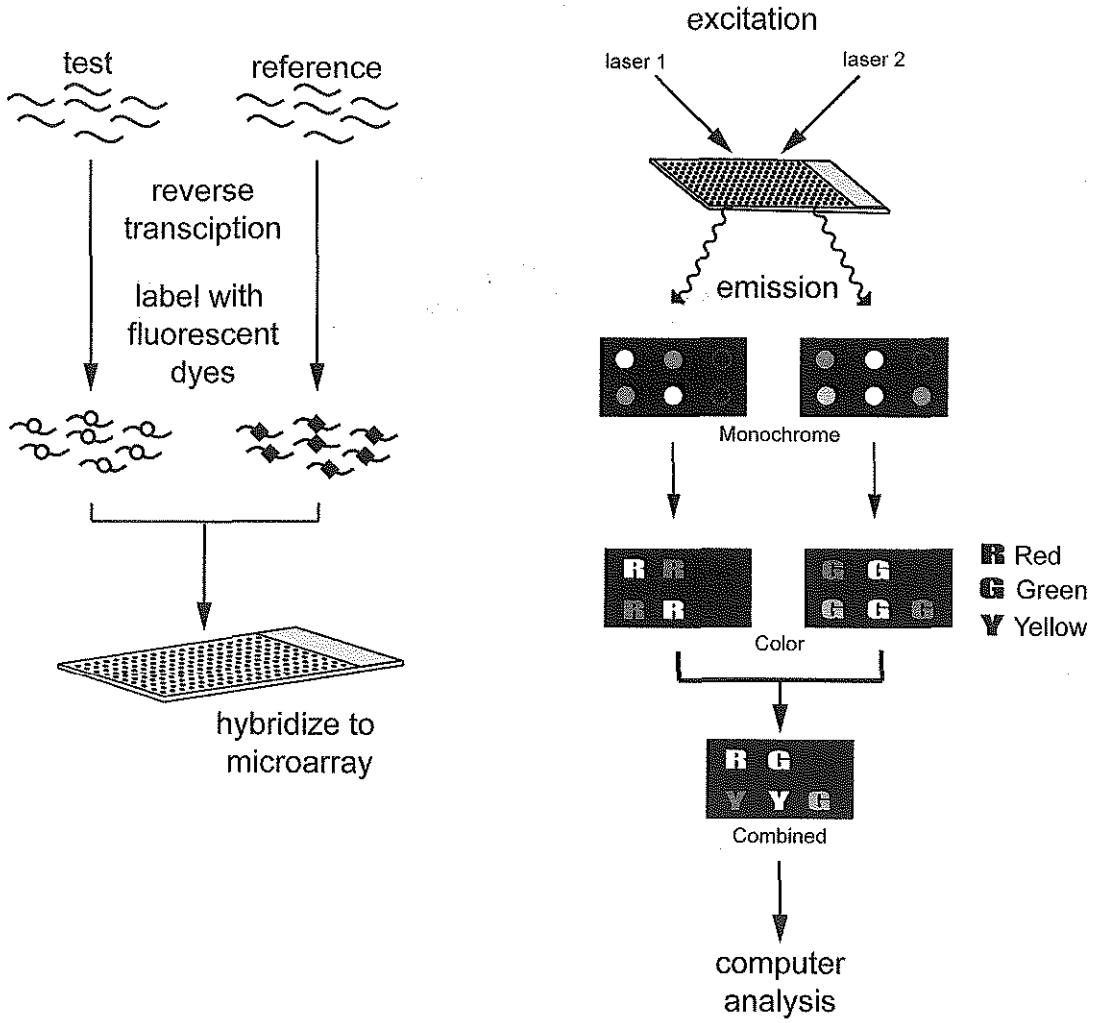

Figure 37-22 A two-color microarray experiment. An array of DNA clones representing expressed-sequence tags (ESTs) is affixed to a glass slide. Messenger RNAs in the test and reference specimen are converted into differentially labeled cDNA by reverse transcription and incorporation of two different fluorescent dyes. The two samples are hybridized together onto the array. The array is washed, and the image is captured twice, each time with a laser of a wavelength that excites one of the dyes but not the other. The monochromatic images are then converted to two colors (green for the test sample [G], and red for the reference [R]), and the images are combined. If the abundance of cDNA is the same in each of the two samples, then the composite spot will be shown as yellow [Y]. If one is in greater abundance, then that color will be preserved. Upregulation and downregulation of gene expression are then analyzed by software.

matrix for hybridization. The process is analogous to immunohistochemistry except that nucleic acids instead of antibodies are used as probes. The strength of the method lies in linking morphological evaluation with detection of specific nucleic acid sequences. When fluorescent probes are applied to metaphase chromosome spreads or interphase nuclei the technique is referred to as fluorescent in-situ hybridization or *FISH*. Detecting numerical aberrations or translocations of chromosomes can be achieved rapidly. FISH can also be combined with immunohistochemistry so that information on both the amount of protein expression and the gene dosage can be obtained on the same slide. In tissue, in situ hybridization is appropriate when localization of a target is important. However, experience in histopathology is necessary for accurate interpretation. In situ hybridization can provide information on the level of mRNA expression, but not on the size or structure of the mRNA. As might be expected, hybridization within a tissue matrix is more variable than in solution or on well-characterized chemical surfaces.

TABLE 37-4 Microarrays and Medium-Density Arrays

Type of Array Surface	What Is Tethered on the Array Surface	Hybridization	Detection
Glass (microscope slides, silicon wafers) Chemically coated transducers (gold electrodes, gold-coated piezoelectric crystals) Microelectrodes coated with gel pad Microsphere beads (4 μm diameter, stained with fluorescent dye)	Oligonucleotide probes (20 to ~80-mers) are synthesized either in situ (on-chip) or by conventional synthesis followed by on-chip immobilization Expressed-sequence tags (200-500 bases long) Sample DNA or cDNA (by electronic addressing)	Typically the array is exposed to labeled sample DNA or labeled sample cDNA (and less frequently to labeled probes), hybridized, and the identity/abundance of complementary sequences is determined	Fluorescence detection: confocal or laser scanning devices, CCD cameras, near-infrared imaging, surface plasmon resonance imaging, flow cytometry (for microspheres) Other: electronic detection, mass spectrometry

Real-Time PCR

In real-time PCR, data are collected during nucleic acid amplification rather than at a single endpoint. The technique uses fluorescent reporter molecules and instrumentation that records fluorescence during thermal cycling. The data obtained provide information on the identity, quantity, and sequence of the nucleic acid sample. Fluorescent dyes or probes capable of signaling the relative quantity of DNA are added to the PCR mixture before amplification. The same reaction tube is used for amplification and fluorescence monitoring, and there are no sample transfers, reagent additions, or gel separation steps, thereby eliminating the risk of product contamination in subsequent reactions. Because the process is simple and fast, real-time PCR is replacing many conventional techniques in the clinical laboratory.

Real-time PCR was first described using ethidium bromide to monitor the accumulation of a double-stranded PCR product with the fluorescence signal recorded once each cycle.[36,37] If target DNA is present, the fluorescence increases. How early during PCR one begins to see a signal depends on the initial amount of target DNA, and this provides a systematic method of quantification. Further, when fluorescence is continuously monitored as the temperature is raised, a melting curve can be generated. Often the first derivative of this melting curve is plotted to visually aid a person in determining the position of the melting temperature. Melting analysis can be used to verify the identity of the amplified product and to detect sequence variants down to a single base (Figure 37-23). Real-time PCR and melting analysis can be considered as "dynamic" hybridization assays in which the formation or dissociation of the probe-target duplex (or product duplex) is monitored in real time.

Dyes and Probe Formats for Real-Time PCR

Many different fluorescent reporter systems are used in real-time PCR, and some of the more common ones are shown in Figure 37-24. Many methods use probes with sequences complementary to the target. Others rely on the specificity afforded by PCR primers, and some have the additional option of melting analysis to verify the melting temperature of the probe or product.

Double-Stranded DNA Binding Dyes

Although ethidium bromide was the first dye used in real-time PCR, SYBR Green I is more commonly used today. Introduced to real-time PCR in 1997,[109] SYBR Green I has fluorescent properties similar to those of fluorescein, allowing the use of commonly available real-time optics. Both ethidium bromide and SYBR Green I exhibit an increase in fluorescence when bound to double-stranded DNA (see Figure 37-24, row one), but the performance of SYBR Green I in real-time PCR surpasses ethidium bromide because of the very low background fluorescence of the free dye, and because it can better distinguish double strands from single strands of nucleic acids.[110] SYBR Green I is commonly used for real-time quantification when the specificity of a probe is not needed and the cost of probes can be avoided.

Fluorescently Labeled Primers

Labeled primers can also be used to monitor PCR. In one system, a primer with a 5′-hairpin is labeled with a fluorophore and a quencher so that fluorescence is quenched in the hairpin conformation. When the primer straightens out during PCR, fluorescence increases[68] (see Figure 27-24, row six). If the sequence of the primer is carefully considered, the quencher moiety is not necessary.[67] Nonhairpin primers

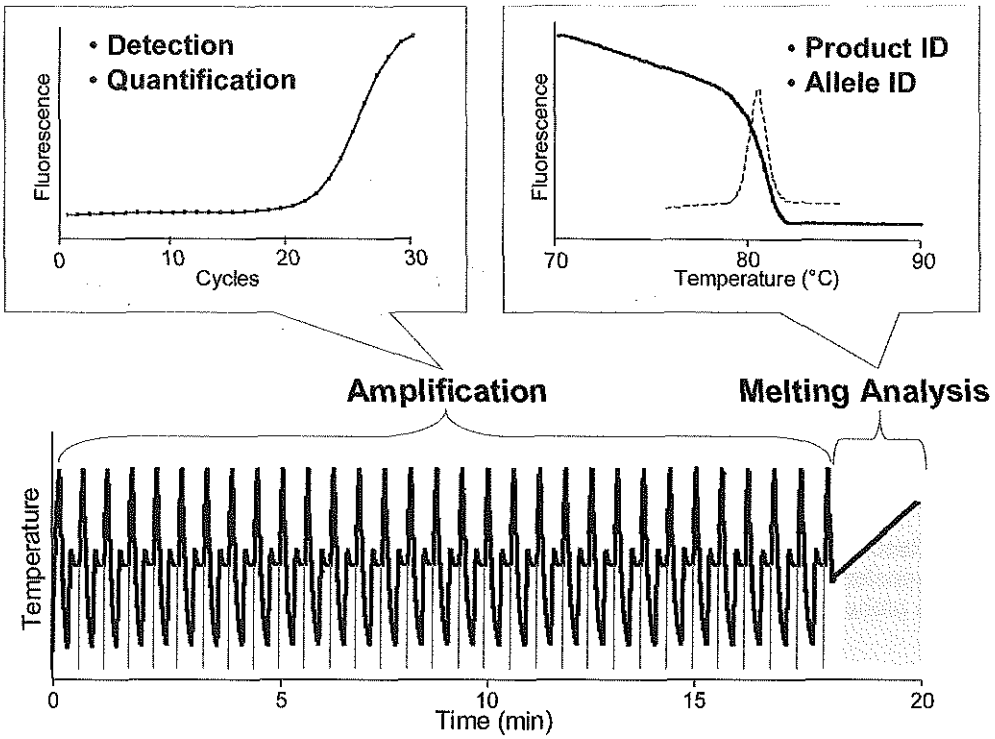

Figure 37-23 Real-time monitoring during amplification and melting analysis. The bottom panel shows a typical rapid-cycle temperature profile that is followed by a temperature ramp for melting analysis. When a signal is monitored during amplification once each cycle *(dotted lines)*, it provides information on the presence or absence of specific target sequences and allows quantification of the target. When a signal is monitored continuously through the melting phase *(shaded area)*, it can provide information that verifies target identification or establishes genotype. *(Modifed with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. In Persing DH, Tenover FC, Versalovic J, Tang YW, Unger ER, Relman DA, White TJ (eds.), Molecular Microbiology: Diagnostic Principles and Practice, Washington, DC: ASM Press, 2004:71-84.)*

with a single label can also be used for detection and genotyping because of changes in fluorescence that occur with hybridization.[31]

One advantage of fluorescently labeled primers over dsDNA dyes is that multiplexing is possible. However, with both dsDNA dyes and labeled primers, reaction specificity depends on the specificity of the primers. Any double-stranded product that is formed will be detected, including primer-dimers. Therefore, hot start techniques, temperature discrimination by collecting real-time data at a high temperature, and melting curve analysis to confirm the desired product are useful.

Probe-Specific Detection

The use of fluorescent probes in PCR provides an additional level of specificity to the process. Fluorescent probes that hybridize to PCR products during amplification change fluorescence by two possible mechanisms: (1) a covalent bond between two dyes is broken by hydrolysis or made through ligation, or (2) the fluorescence change follows reversible hybridization of the probe to the target. Following this distinction, when an irreversible covalent bond is involved, the probes are called *hydrolysis probes*. When probes reversibly change fluorescence on duplex formation, they are called *hybridization probes*. One major difference between the two probe types is that melting analysis is possible with hybridization probes, but not with hydrolysis probes.

Hybridization Probes. These probes change fluorescence upon hybridization, usually by fluorescence resonance energy transfer.[53,109] Two interacting fluorophores may be placed on adjacent probes (see Figure 37-24, row two), or one may be placed on a primer and the other on a probe (see Figure 37-24, row three). Only one probe with one fluorophore may be necessary if the fluorescence is quenched by deoxyguanosine residues.[19] Another single-labeled probe design uses thiazole orange attached to a peptide nucleic acid.[94] In each of these designs, the fluorescence change of hybridization probes is reversible with melting.

Hydrolysis Probes. A fluorophore-labeled probe can be synthesized with a quencher located in a position that allows

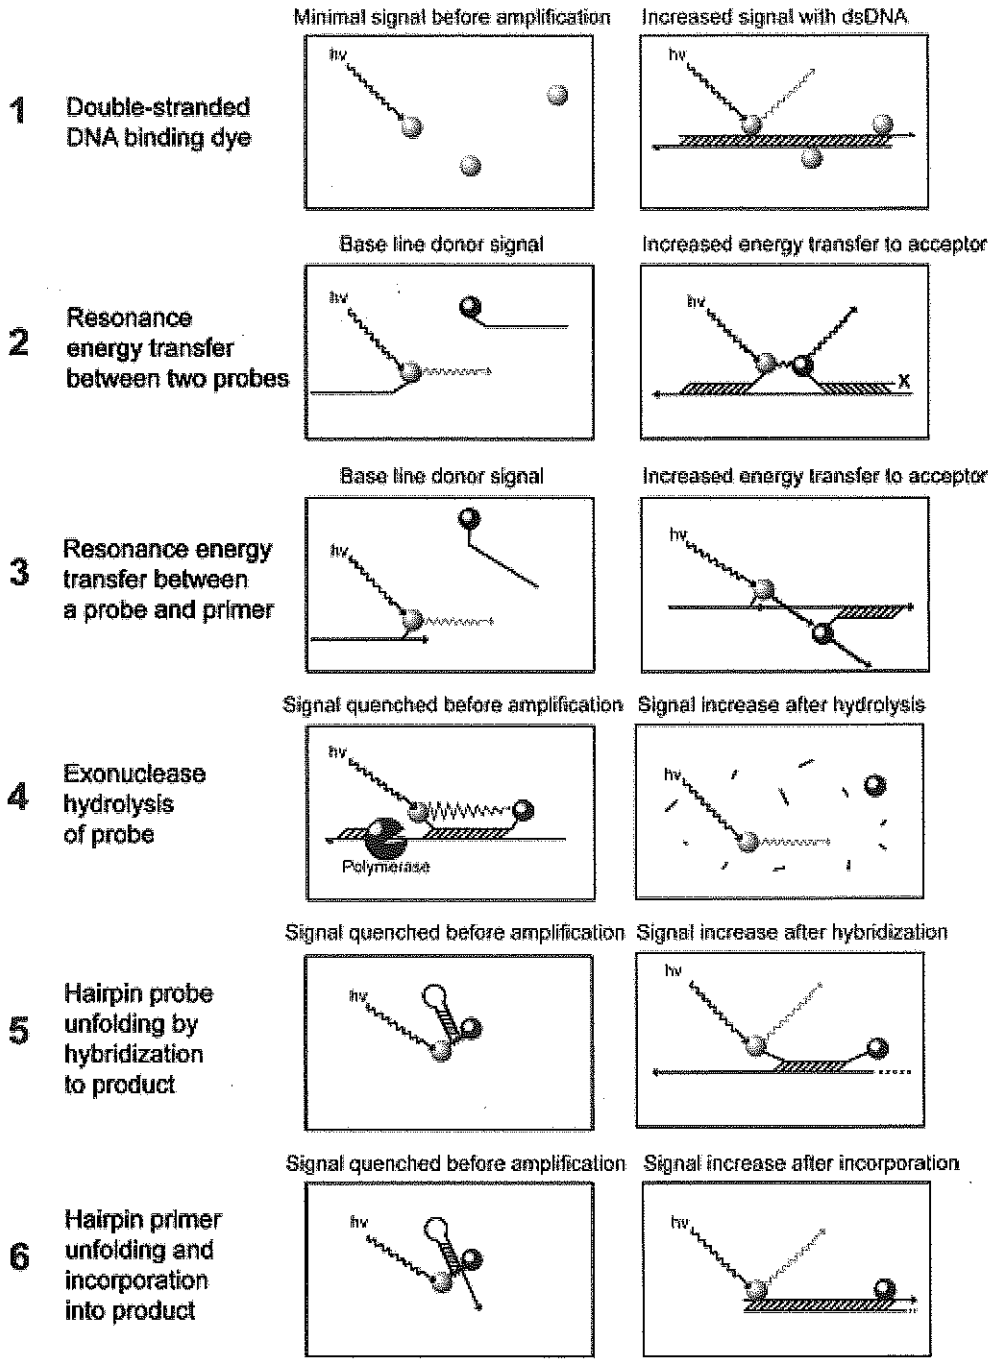

Figure 37-24 Common probes and dyes for real-time PCR. *(1)* Double-stranded DNA dyes show a significant increase in fluorescence when bound to DNA (*hv* = excitation light). *(2)* Adjacent hybridization probes. Fluorescence resonance energy transfer (FRET) is illustrated between a donor and acceptor fluorophore. The "x" indicates phosphorylation of the 3′ terminus of the probe to prevent polymerase extension. *(3)* FRET between a labeled primer and a single hybridization probe. *(4)* Hydrolysis probes are cleaved between the reporter and quencher, resulting in increased fluorescence. *(5)* Hairpin probes are quenched in the native conformation, but increase in fluorescence when hybridized. *(6)* Hairpin primers retain their native, quenched conformation until they are incorporated into a double-stranded product. *(Modified with permission of the publisher from Pritham GH, Wittwer CT: Continuous fluorescent monitoring of PCR. J Clin Lig Assay 1998, 21:404-412. © 1998 Clinical Ligand Assay Society, Inc.)*

it to quench the fluorescence from the fluorophore. If the probe is hydrolyzed during PCR between the fluorophore and the quencher, fluorescence will increase. The most common implementation uses the 5′-exonuclease activity of the DNA polymerase to hydrolyze the probe and dissociate the labels (see Figure 37-24, row four). This method has been simplified by putting the fluorophores on opposite ends of the probe.[58] Hybrid-stabilizing agents, such as a minor-groove binder, can be added to the probe to make the system more robust.[46] Dual-labeled probes can also be cleaved using a DNAzyme (a DNA molecule that acts as a catalyst) generated during PCR.[96] Finally, irreversible ligation can also be used for homogeneous genotyping with a fluorescent readout.[16] Hydrolysis probes generate fluorescence through changes in covalent bonds. The change in fluorescence signal is irreversible, and melting analysis of the hydrolyzed probe is not useful.

Mixed Mechanism Probes. Several probe systems appear to function by both hydrolysis and hybridization mechanisms. These include hairpin probes, self-probing amplicon primers, and displacement probes. A hairpin probe functions similarly to a hairpin primer in that it is designed to increase in fluorescence when the distance between the quencher and the reporter increases upon target hybridization (see Figure 37-24, row five). Similarly, primers that result in self-probing amplicons have a hairpin that separates quencher from reporter when hybridized.[104] Competitive displacement probes separate quencher and reporter by competitive hybridization.[56] However, in all three cases, polymerases with exonuclease activity are usually used and the labeled probes are potential substrates for exonuclease cleavage. Indeed, the fluorescence versus cycle number plots often resemble irreversible hydrolysis rather than reversible hybridization (Figure 37-25). Conversely, many exonuclease probes, especially probes labeled on each end, show significant hybridization signals.[58]

Detection and Quantification in Real-Time PCR

When fluorescence is monitored once each cycle in the presence of SYBR Green I, the data closely follow the expected logistic shape discussed earlier (see Figures 37-3 and 37-25 top left). However, with hydrolysis probes, fluorescence is cumulative and continues to increase even after the amount of product reaches a plateau (see Figure 37-25, top middle). In contrast, reactions monitored with hybridization probes may show a decrease in fluorescence at high cycle number[112] (see Figure 37-25, top right). Despite differences in curve shape, all real-time systems follow the amount of product being produced during PCR, and this information is used for detection and quantification.

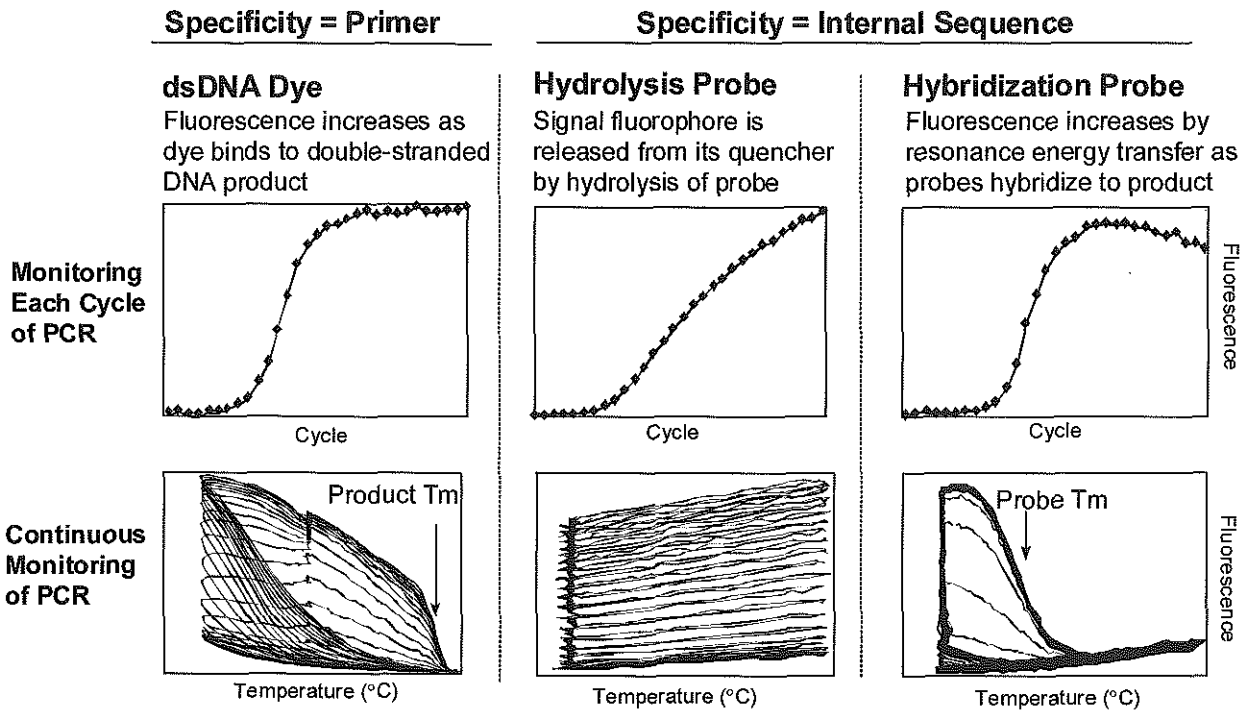

Figure 37-25 Monitoring in real time. The top row shows data collected once each PCR cycle, and the bottom row shows data collected continuously (5 times per second) during all PCR cycles. Three different reporter systems are shown. *(Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. *The number of cycles that separates each decade difference in initial template concentration (Cycles/log [DNA]) is 1/log (efficiency). The calibration curve slope is the negative of this value (−1/log (efficiency)), assuming the log [initial template] is plotted on the *x*-axis as the independent variable, and cycle number is plotted on the *y*-axis as the dependent variable.

Detection

A fluorescent signal that increases during PCR and follows one of the expected curve shapes suggests that the specific target is present and was amplified. In contrast, a signal that stays at background even after 40 to ~50 PCR cycles suggests that the target is absent and that no amplification occurred. Algorithms that analyze the entire curve are more robust than simple threshold methods.[110] Adequate positive controls (to rule out inhibitory factors) and adequate negative controls (to rule out product contamination and nonspecific signal generation) are necessary. If the fluorescent signal is reversible with hybridization, melting analysis can be used to verify the expected Tm of the probe or product.

When specificity of the assay depends upon the specificity of the primers ("primer-specific detection," as is the case when DNA dyes or labeled primers are used), the possibility of unexpectedly amplifying other targets or primer-dimers is a concern. One way to eliminate or decrease the detection of unexpected targets is to acquire fluorescence during each cycle at a temperature just below the melting transition of the expected target. To illustrate the concept, Figure 37-26 shows a first-derivative melting curve of products at the end of a PCR that generated unexpected products along with the desired product. The signal was generated with SYBR Green I, a dye that detects all double-stranded DNA. The plot reveals both lower Tm species that are unexpected products and a single Gaussian-shaped peak that is centered on the target's predicted Tm. If fluorescence is acquired during each cycle at (in this case) 85 °C, the unexpected products will be denatured and will not contribute to the signal.

Multiplexing of detection is possible with probes that are labeled with different-color dyes or with probes that have different melting temperatures. For example, probe multiplexing can be used to detect the presence of more than one infectious organism, or to discriminate an internal control template from the target.

Quantification

Real-time PCR offers a convenient and systematic approach to quantification by monitoring the amount of product each cycle. Perhaps the most popular clinical use of real-time PCR is in the assessment of viral load, particularly for HIV and HCV. The clinical need for quantification is well established and real-time methods give rapid and precise answers. However, other amplification systems, particularly transcription-based and branched DNA methods, are also popular in this highly competitive field. Additional quantitative applications of real time PCR include quantification of mRNAs (after reverse transcription) in gene-expression studies and assessment of gene dosage in genetics and oncology.

One of the advantages of real-time PCR is its large dynamic range. Figure 37-27, *A* shows an extended range of external calibrators in a typical real-time PCR. As the initial template concentration increases, the curves shift to earlier cycles. The extent of the shift depends on the PCR efficiency (Table 37-5). The cycle at which fluorescence rises above background correlates inversely with the log of the initial template concentration (Figure 37-27, *B*). This "cycle" is actually a *virtual* cycle that includes a fractional component determined by interpolation, which can be calculated by several methods. The most precise of these methods is to take the *second derivative* of the curve and determine the cycle number from the maximum point (Figure 37-28). The second derivative of the amplification curve is estimated numerically with Savitzky-Golay polynomials.[78] The second derivative is derived from the shape of the curves and there is no need to adjust baselines or worry about normalizing the fluorescence values. Other methods include *threshold analysis* where a fluorescence level is selected that intersects

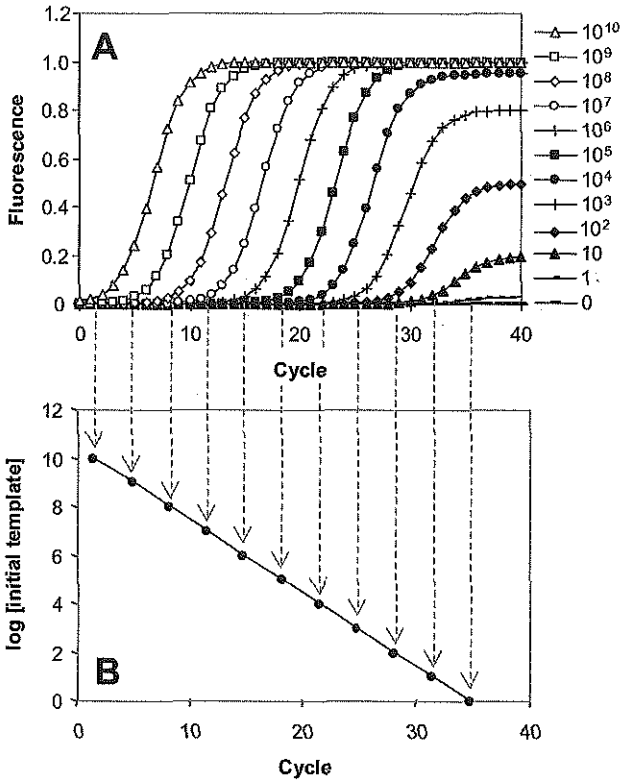

Figure 37-27 Quantification by real-time PCR. Shown are typical real-time curves for amplification reactions of varying initial target concentrations (panel A), and the log of the initial concentration plotted against the cycle number at which the signal rises above background (panel B) as calculated by the second derivative maximum (see Figure 37-28). *(Modified with permission of the publisher from Wittwer CT, Kusukawa N. Real-time PCR. with the amplification curves. The fractional cycle number of each curve is found by interpolation and is known as the *cycle threshold* or C_t. However, when the sample fluorescence does not reach the threshold (as may happen with low copy samples), quantification is not possible. The fractional cycle number can also be determined by *fitting points to an exponential.* The number of points in the log-linear portion of each amplification curve is found by inspection on a log-linear plot. The intersection of a line through these points and a set fluorescence level is known as the *crossing point,* or C_p. In both the C_t and C_p methods, it is necessary to adjust the fluorescence baseline before comparing different samples. In some cases, subtraction of a no-template control may eliminate irrelevant signals. Usually an early cycle interval is chosen (e.g., cycles 5 to 10) to represent the baseline. In *arithmetic adjustment,* all baselines are adjusted to zero by subtracting a curve-specific constant. In *proportional adjustment,* the baseline is first adjusted to 1.0 by dividing by a curve-specific constant, followed by subtraction of 1.0 from all points to bring the baseline to zero. Amplification curves can also be *normalized* to between 0.0 and 1.0 with the equation $F_{normalized} = (F_{measured} - F_{min})/(F_{max} - F_{min})$.

Accuracy and Precision

The accuracy of real-time PCR quantification depends not only on the method chosen to analyze the curves, but also on the quality of calibrators used. Purified PCR products quantified by spectrophotometry are easily obtained. When serially diluted, these calibrators can accurately quantify the amount of target in human genomic DNA.[78] Alternatively, purified plasmids or genomic DNA can be used as calibrators. Limiting dilution analysis to determine the amount of "amplifiable" DNA is seldom necessary.[64] The precision of quantitative real-time PCR depends on the copy number. When the initial target concentration is low, imprecision is high. Part of the variance comes from stochastic limitations as defined by the Poisson distribution as described earlier. In addition, the PCR efficiency may be more variable at low copy numbers.

Melting Analysis

Not only can amplification, detection, and quantification be performed by homogeneous hybridization, but detailed genotyping information can also be obtained. Genotyping is best performed in the same tube by monitoring the melting of hybridized duplexes during controlled heating, producing a melting curve signature for the duplex. Such a signature monitors duplex binding over of a range of temperatures in

contrast to the single-temperature analysis of conventional hybridization techniques, such as dot blots or microarrays. The advantages of complete melting curves also apply when considering only homogeneous techniques. For example, methods that rely on hydrolysis for signal generation and/or those that acquire data only at one temperature generally result in more genotyping errors.[95] Amplification and melting analysis is a powerful combination of techniques that only requires temperature control and sampling of fluorescence. Many other genotyping techniques require complex separation and/or detection equipment after PCR. Real-time PCR with melting curve analysis allows detection, quantification, and genotyping in less than 30 minutes (see Figure 37-23) without ancillary processing or additional equipment. A book series has been published on methods and applications of rapid-cycle, real-time PCR.[22,62,80,108]

When fluorescence is monitored continuously within each cycle of PCR, the hybridization characteristics of PCR products and probes can be observed. In the plots of fluorescence versus temperature (see Figure 37-25, bottom panels), fluorescence is monitored five times a second during rapid-cycle PCR.[109] With SYBR Green I, the melting characteristics of the amplified DNA can identify the product.[83] No hybridization information is revealed with hydrolysis probes, whereas the melting of hybridization probes is readily apparent. Probe melting occurs at a characteristic temperature that can be exploited to confirm target identity and to analyze sequence alterations under the probe. For routine testing in the clinical laboratory, a single melting curve is usually performed at the end of PCR instead of monitoring hybridization throughout the entire PCR process (see Figure 37-23).

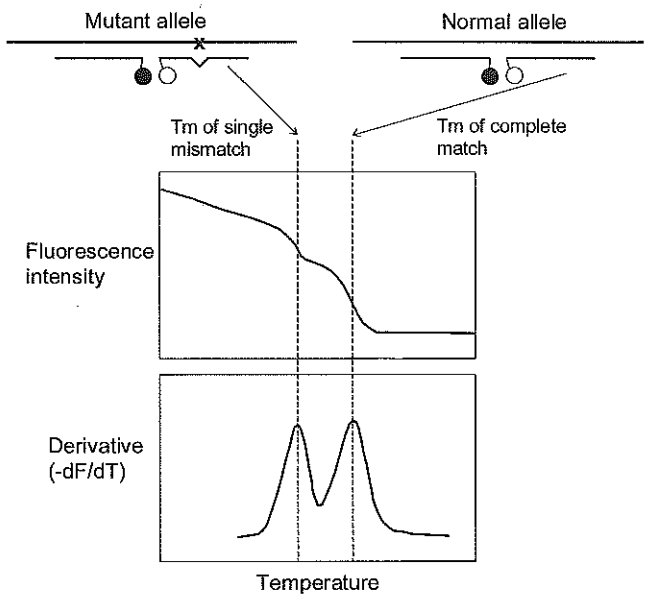

Figure 37-29 Melting curve SNP genotyping. A heterozygous specimen with an SNP under the probe is amplified and melted. Two temperature transitions are visible, one from the mutant allele that is mismatched with the probe and melts at a lower temperature, and one from the normal allele that is completely matched with the probe and melts at a higher temperature. The derivative plot shows the melting temperatures of both the mutant-probe and the normal-probe duplexes as peaks. *(Modified with permission of the publisher from Bernard PS, Pritham GH, Wittwer CT: Color multiplexing hybridization probes using the apolipoprotein E locus as a model system for genotyping. Anal Biochem 1999, 273:221-228. © 1999 Academic Press.)*

Melting Protocols

Immediately after the last PCR cycle, the samples are momentarily denatured (90 °C to 94 °C) cooled to about 10 °C below the Tm range of interest, and finally heated at a ramp rate of 0.1 °C to 0.3 °C while continuously monitoring fluorescence. When hybridization probes are used, the cooling protocol should maximize formation of probe-target duplexes while minimizing formation of the duplex PCR product. Minor primer asymmetry (1:2 to 1:4) and use of 5′-exonuclease–deficient polymerases may be helpful. Rapid cooling (at rates of ~20 °C/sec) to 10 °C above the Tm interest range, followed by slow cooling at 0.1 °C to 1.0 °C/s to 10 °C below the interest range, favors probe-target duplex formation of all alleles.

SNP Detection by Melting Curve Analysis

A hybridization probe-pair placed over a heterozygous polymorphism is shown in Figure 37-29. The reporter probe is complementary to the normal allele. As the temperature is increased, the mismatched mutant hybrid melts first, giving the first transition, followed by the matched normal hybrid. The melting temperatures of both hybrids are easily seen in the derivative plot generated by numerical Savitzky-Golay polynomial estimation.[78] A well-optimized probe design will provide a Tm difference of 8 °C to ~10 °C for a single base mismatch under the probe. The calculation for the baseline in the derivative plot assumes that there are two stable states of fluorescence, one on each side of the transitional region, that depend linearly on temperature (as does fluorescence from a pure fluorophore in solution). After baseline subtraction, each transition can be quantified by fitting multiple Gaussian curves by nonlinear least squares regression.

SNP genotyping by melting curve analysis can be achieved with a variety of probe and dye methods. The top row of Figure 37-30 shows the design of traditional hybridization probe pairs[9] and the results of homozygous wild-type, mutant, and heterozygous samples that are well discriminated from each other. Virtually the same result can be achieved by use of a single hybridization probe in which the fluorescent signal is quenched on the free probe, but dequenched as it forms a hybrid with the target (second row)[7]. The third row shows a design in which no probe is used, and the signal is provided by either a labeled primer that is incorporated into the amplicon[31] or a DNA binding dye[57]; the melting profile of the PCR product is used for genotyping. Finally, the last row shows a design with

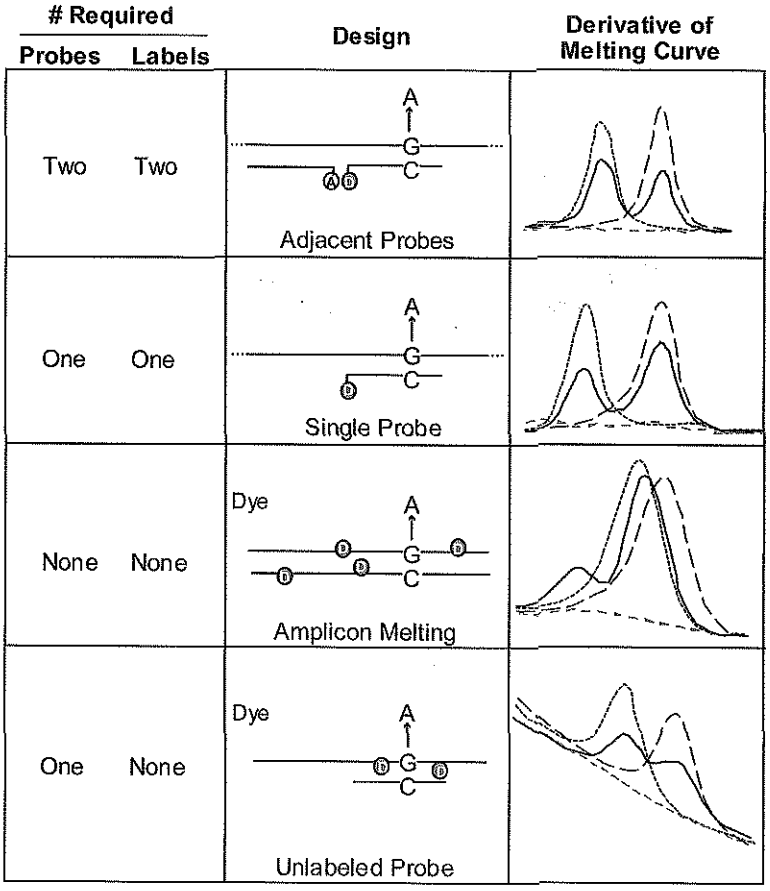

Figure 37-30 Four modes of SNP genotyping by melting analysis. The traditional hybridization-probe design *(top row)* uses a pair of probes, one labeled with an acceptor fluorophore *(circle A)* and the other with a donor fluorophore *(circle D)*. The single-hybridization-probe design *(second row)* lacks the second probe. The amplicon melting design *(third row)* uses a saturating double-stranded DNA binding dye. The two homozygotes, although close in Tm, can usually still be differentiated, and the heterozygote has an additional low-temperature transition caused by heteroduplexes. The unlabeled-probe design *(bottom row)*, similar to amplicon melting, does not require a covalently attached fluorescent label and uses a DNA binding dye. However, because a probe is used, the derivative melting curves are better separated than with amplicon melting. Homozygous G allele (*dashed line* in far right column), homozygous A allele *(dotted line)*, and the GA heterozygote *(solid line)*.

unlabeled probes and DNA binding dyes.[115] The last two methods are advantageous in that fluorescently labeled oligonucleotides are not required.

Mutation Scanning by Melting Curve Analysis

In earlier sections of this chapter, detection of heteroduplexes (either by electrophoresis or HPLC) was discussed as a means to scan stretches of DNA in which the presence of a polymorphism is suspected. Melting analysis can be used to detect heteroduplexes with equal or better sensitivity than these methods without the necessity of taking the amplified reaction mixture out of its tube. This is achieved by the use of saturating concentrations of a double-stranded, DNA-binding dye that does not inhibit PCR, with the aid of a high-resolution melting instrument.[111] High-resolution melting analysis can be performed in 1 to 2 minutes. The data are normalized between 0% and 100% fluorescence and the curves shifted in temperature to overlap at low fluorescence levels. An example of heteroduplex detection and SNP genotyping by melting curve analysis is shown in Figure 37-31. The PCR product was over 500 bases in length and the melting curve split into two clear melting domains. The SNP was present in the lower melting domain and all genotypes are distinguishable. Melting analysis has been used to scan for c-kit activating mutations in gastrointestinal stromal tumors[106] and to establish HLA genotypic identity.

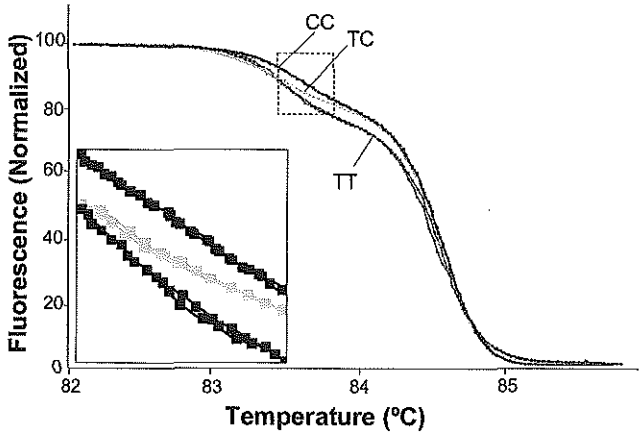

Figure 37-31 A single-nucleotide polymorphism demonstrated in a 544-bp fragment by melting analysis. Shown are high-resolution melting curves of PCR amplicons from the HTR2A gene locus carrying an SNP. Results are shown for six individuals, two different individuals for each of the three genotypes: wild-type homozygote (TT), mutant homozygote (CC), and heterozygote (TC). In the inset is a magnified portion of the data showing that all three genotypes can be discriminated. *(Modified by permission of the publisher from Wittwer C.T., Reed G.H., Gundry C.N., et al. High-Resolution Genotyping by Amplicon Melting Analysis Using LCGreen. Clin Chem 2003;49:853-60. © AACC.)*

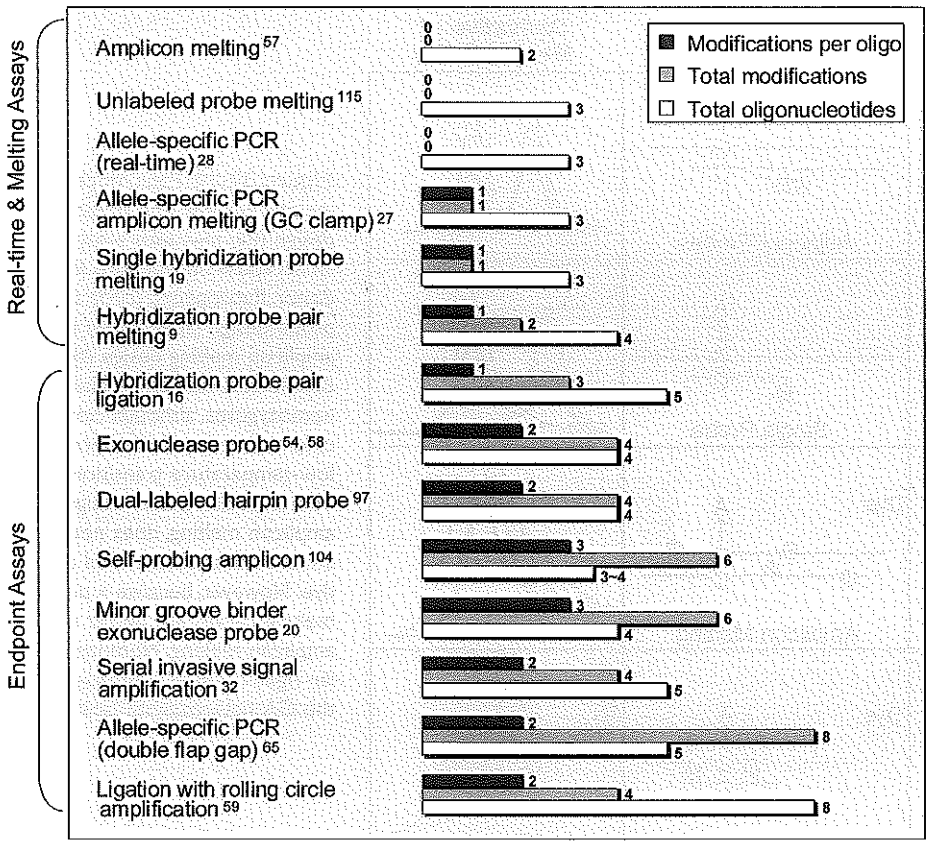

Figure 37-32 Closed-tube methods for SNP typing. Methods are listed from top to bottom in ascending order of complexity. Modifications to oligonucleotides usually involve additions of fluorophore or quencher, but occasionally 5′-tail additions of nucleotides. Endpoint and melting assays do not require signal acquisition during PCR. Melting analysis of amplicons and hybridization probes can detect more than two alleles, although all other techniques will detect only two. References to each technique are given as superscripts.

Comparison of Closed-Tube SNP Genotyping Methods

There are many methods for SNP genotyping and the method of choice depends on several factors, including turnaround time and throughput requirements. The necessities of high-volume genomic research are different from a clinical reference laboratory, a medical clinic, or the STAT laboratories of the future.

Methods for homogeneous SNP analysis in a closed-tube system differ greatly in their level of complexity (Figure 37-32). The number of oligonucleotides required varies from 2 to 8. The simpler techniques do not require probes at all, although some of the more complex techniques require up to three labels or modifications on each probe. All of these methods use fluorescence and solution hybridization. Some of the methods that use melting analysis will detect more than two alleles if present; those based on allele-specific amplification or endpoint analysis are limited to two.

The four simplest methods do not even use fluorescently labeled probes. Amplicon melting uses only two primers and a double-strand DNA dye (see Figure 37-30, row three). Unlabeled probe genotyping requires three oligonucleotides and a DNA dye (Figure 37-30, bottom row). Allele-specific PCR requires three primers and is based on a preference by the polymerase to extend only a perfectly matched primer. By monitoring the reaction each cycle, genotyping and even allele frequencies in pools of DNA can be determined.[28] Instead of real-time analysis, allele-specific PCR can incorporate a GC-clamp into the product of one allele, so that alleles can be differentiated at the end of PCR by the melting temperature.[27] Intermediate in complexity are hybridization-probe-melting assays. Designs with a single hybridization probe or a pair of probes are shown in Figure 37-30 (first and second rows).

The more complex closed-tube methods for SNP genotyping are endpoint assays. In hybridization-probe-pair ligation, irreversible ligation of adjacent probes results in fluorescence resonance energy transfer.[16] Allele-specific 5′-exonuclease and hairpin probes are commonly used methods. Self-probing amplicons and minor-groove binder 5′-exonuclease probes[20] both require three modifications on two probes for SNP typing. Serial invasive signal amplification is a method of homogeneous genotyping that does not

require PCR. Allele-specific PCR can be linked to hydrolysis of a dual-labeled probe by formation of a double flap gap.[65] Finally, ligation can be used to join two ends of a long, single "padlock" probe if and only if both ends perfectly anneal to adjacent sites on the target. The resulting circle can be amplified by rolling circle amplification.

CONCLUSION

Molecular diagnostics remains a trendy, developing field in laboratory medicine. Current progress in nucleic acid techniques is extraordinary, driven by the promise of great return. Can drug therapy be tailored to each individual by appropriate molecular tests? Can diagnostic biochips parallel the microelectronics revolution, continuing to provide more information at less expense? Will complete genome sequencing for individual predisposition testing become a reality? Although we are still years away from the Star Trek tricorder, the time for immediate personalized diagnostics will come. To boldly explore these new frontiers, current and future analysis techniques will provide the starship. Indeed the rate-limiting factor is usually in establishing the biological correlations, not the sophistication of the techniques to analyze nucleic acid. Nevertheless, simple, powerful, and cost-effective techniques will get us there sooner.

Techniques for molecular analysis often require multiple steps, including sample preparation, amplification, and analysis. As a result, successful automation is critical for their routine adoption in the clinical laboratory. However, to corruptly paraphrase Henry David Thoreau in Civil Disobedience—"I heartily adhere to the motto: The best automation is not needing to automate." The simplest techniques are often the best. As for immunoassays, methods that require separation and washing steps are being replaced with nonseparation methods that are rapid and homogeneous. These and other simple methods hold great promise for the clinical laboratory.

CHAPTER 38

Design and Operation of the Molecular Diagnostics Laboratory

Anthony A. Killeen, M.D., Ph.D.

INTRODUCTION

The design and operation of a molecular diagnostics laboratory have much in common with other areas of the clinical laboratories. The purpose of this chapter is to highlight specific issues that are unique to a molecular diagnostics laboratory, both in design and operation.

CENTRALIZATION OR DECENTRALIZATION?

Molecular techniques are of importance in clinical diagnostics in most disciplines of laboratory medicine and pathology and their applications will continue to grow in essentially all areas of testing. These considerations raise a fundamental question in the design of a laboratory system: should each discipline that uses molecular techniques have its own molecular laboratory space or is a centralized molecular laboratory a more suitable model to deliver molecular testing services? The answer will depend to a large degree on local factors, but has significant implications for the overall costs and efficiencies of providing molecular testing services. The major argument in favor of centralization is the efficiencies achieved through sharing of equipment, reagents, personnel, and space. On the other hand, the adoption of molecular techniques in areas as diverse as microbiology and inherited diseases requires a broad range of specialist skills and knowledge that may be difficult to develop in a centralized laboratory. In addition, certain molecular tests may be integral to the activities of another laboratory, thereby precluding their performance in a central molecular testing facility. For example, many hospital laboratories use a dual system in which a central laboratory performs tests in areas such as molecular genetics and molecular oncology, whereas molecular techniques for advanced microbial identification and characterization are performed in the existing microbiology laboratory.

CHOOSING A TEST MENU

Factors that influence the decision to offer a test include the local demand, the resources available to perform the test, the skills and interests of the personnel, particularly the laboratory director, the likelihood of the test being financially viable, and whether the test is, in whole or part, patented or has other intellectual property restrictions.

Local demand for testing will most likely come from clinicians who are looking for tests to help with patient diagnosis and management. Such demands should be carefully evaluated to ensure that clinician expectations can be reasonably met in a cost-effective manner. Higher volume tests tend to improve the overall financial stability of a laboratory because the fixed costs become a smaller proportion of the individual test cost. Conversely, it seldom makes financial sense to offer low-volume tests unless reimbursements are sufficiently high to cover the costs. However, volumes may increase if the laboratory can become a regional or national referral center for a test. If a clinician has expertise in a clinical area that stimulates test ordering, it is possible that offering a laboratory test may enhance the ability of the clinical service to attract increased recognition, more patients, research support, and other external funding. Thus what seems at first to be a low-volume test may with time become an important item in the laboratory's and institution's repertoire. A further consideration in selecting the test

menu is the ability to deliver acceptable turnaround times. Expectations for turnaround time, and therefore the frequency with which tests must be performed, vary with the analyte. For example, tests for infectious agents usually require a shorter turnaround time than do tests for chronic, inherited diseases. Expectations of a short turnaround time tend to increase the analytical cost per sample, while at the same time indicate the need to offer a test in house rather than send samples to an external laboratory.

SPACE AND DESIGN CONSIDERATIONS

The major consideration in the physical layout of a molecular diagnostics laboratory, other than adequate space, is a design that prevents or helps control contamination. The use of polymerase chain reaction (PCR) and other target amplification methodologies can introduce an important source of laboratory error, namely, contamination of the laboratory with amplicons from previous reactions. These can be introduced in the laboratory environment when a tube containing amplicons is opened and a small amount of the solution becomes an aerosol. Without careful laboratory technique, amplicons can be spread to new samples and reagents by airborne droplets, gloves, skin, pens, paper, and pieces of equipment, such as pipettes. Because each amplicon can be replicated in a subsequent amplification reaction, an amplicon that contaminates a new patient sample or a reagent solution can lead to an erroneous result, usually a false-positive determination. Contamination of the laboratory by amplicons is a serious problem that often requires extensive decontamination and every precaution should be taken to prevent this problem.

Historically the design of the laboratory has been an important factor in controlling contamination, and the most common design feature that is unique to the molecular diagnostics laboratory has been use of separate rooms for set up and analysis of target amplification reactions. Some laboratory designs also incorporate a positive pressure air control system to prevent airflow from the analysis room to the sample set up or reagent preparation rooms. The air from the analysis room may be vented directly to the exterior of the laboratory building. Such design features can be implemented more easily when planning new construction than when attempting to adapt space in an older building for use as a molecular diagnostics laboratory. If multiple rooms are unavailable, consideration should be given to using laminar flow hoods that contain an ultraviolet light. UV-induced cross-linking of DNA can minimize the effects of amplicon contamination during sample set up.

Other methods to avoid contamination involve meticulous laboratory practice by personnel. The flow of operations from sample receipt to amplified product analysis involves a sequential series of steps that tend from "clean" to "contaminated." It therefore follows that there should be no movement of reagents or equipment in the reverse direction to this flow. For example, pipettes that are used in the post-PCR area should never be introduced into a pre-PCR area. Laboratory coats that are worn in the post-PCR area should be removed before entering a pre-PCR area. Gloves should be discarded after use in the post-PCR area. Laboratory benches should be regularly cleaned using amplicon decontaminating agents, such as solutions of bleach.

Modifications to the procedures used can also reduce contamination. Reagent strategies, such as the use of uracil in PCR reactions combined with preincubation of samples with uracil *N*-glycosylase (UNG), can minimize the risk of contamination.[11] Commercially available systems have been developed that use a closed analytical system (i.e., reaction tubes that are analyzed without being opened). Finally, there are alternative laboratory methods to PCR that do not involve target amplification. These include several methods generally known as "signal amplification" techniques.[8] Depending on the laboratory space (particularly if only limited space is available) and the desired test menu, use of such techniques may be preferable to target amplification methods.

OPERATIONAL CONSIDERATIONS

As mentioned previously, only operational details that are specific for a molecular diagnostics laboratory are discussed here. Many of these involve regulatory issues that are relevant to practice within the United States and may vary between jurisdictions. They are provided here for general guidance.

DOCUMENTS, RECORDS, SAMPLE RETENTION

Compared to past laboratory testing, newer molecular testing sometimes has unique information needs and sample storage requirements. Requisitions, consent, records, and sample retention are reviewed in this section.

Requisitions

As with all requests for testing, the requisition form should indicate patient identifying information, the ordering physician's name and contact information, the sample type, the time of collection, and the test to be performed. For genetic testing, it is common that the requisition form will solicit information on relevant family history that is often provided as a hand-drawn pedigree diagram. Such information can be essential for test interpretation and should be available to the testing laboratory.

Consent for Genetic Testing and Privacy of Medical Records

Much more attention is given in the medical literature to the need for informed consent for genetic testing than to most areas of laboratory testing. The principal reason for this is that by testing for inherited disorders, information may be obtained that has diagnostic or risk implications for other family members. In addition, genetic testing may indicate a high probability of development of symptomatic disease

later in life in patients who appear well at the time of testing. Patients and families may be stigmatized by a diagnosis of genetic disease and may suffer discrimination in employment and in insurability. Although the number of documented cases of such discrimination is few, the fear of adverse consequences of genetic testing is quite common. For these reasons, obtaining informed consent for genetic testing is a common practice and is required by law in many states.[6]

Record Keeping

Under current U.S. federal guidelines, the following records must be retained for at least 2 years for all laboratory testing: specimen requisitions, patient test results and reports, instrument printouts, accession records, quality control records, instrument maintenance records, proficiency testing records, and quality improvement records. Laws concerning records for paternity and forensic testing vary by state; it is the responsibility of the director to assure all applicable regulations are met.

Retention of Extracted Nucleic Acids

Under current federal law, there is no minimum length of time for which an extracted sample of DNA or RNA must be stored after analysis is complete, although regulations do exist for retention of the primary sample. Because extracted samples tend to be of small volume (measured in microliters), many laboratories retain samples indefinitely. However, some states, acting out of concerns for genetic privacy, have proposed or enacted legislation that requires destruction of samples for genetic testing after analysis is complete. These laws vary widely and often specify exceptions (e.g., for samples used in forensic work). Laboratory directors are responsible for following the requirements of their own jurisdictions.

Personnel

The qualifications of personnel are determined by regulatory agencies and by the availability of suitable staff. In the United States, the qualifications for director, technical supervisor, and medical technologists are provided in the Clinical Laboratory Improvement Amendments.[1]

Directorship

The laboratory director should be qualified to direct a high-complexity laboratory. Under current U.S. regulations, federal law requires no formal experience in molecular diagnostics. However, because of the need to issue an interpretation of many molecular diagnostic test results, the director should ideally have training that includes experience in at least one major area of molecular laboratory activity, such as molecular genetics, oncology, infectious diseases, or identity testing. The expertise of the director may need to be complemented by additional personnel with appropriate training, including associate directors with expertise in areas of relevance to the test menu (e.g., hematopathology, genetics, and microbiology).

Technical Personnel

The most suitable educational background for a medical technologist in a molecular diagnostics laboratory is completion of a medical technology training program, including training or experience in molecular diagnostics. However, few medical technology programs produce graduates with specific skills in molecular diagnostics, and thus there is often a need for extensive on-the-job training of newly hired personnel.

Individuals with skills in molecular biology but without formal training in medical technology may be an alternative source of personnel in some geographical areas, but their employment may be contingent on local legal standards for employment within a clinical laboratory (e.g., state licensure requirements). Such individuals often have a strong theoretical background and possibly extensive laboratory experience (often in a research setting), but it is important to recognize that there are specific skills acquired in a formal medical technology program and that the clinical laboratory is a different environment than a research laboratory. This is particularly true in the areas of quality control and abiding by standard procedures.

Result Reporting

Specific guidelines for reporting molecular pathology test results in the United States can be found in the "Molecular Pathology Checklist" from the College of American Pathologists (CAP).[2] In general, information that should be included in reports of genetic testing include details of the methods used including all probes and restriction enzymes, the locus and mutations tested, the findings, and an interpretive report. When mutation testing is incomplete because not all possible disease-causing mutations are examined, the report should indicate the false-negative rate. For example, the recommended panel for cystic fibrosis carrier screening in the U.S. population includes a basic set of only 25 of the >1000 known mutations. This abbreviated panel can detect 80% to 85% of mutations in Caucasians. The false-negative rate for mutation identification is therefore 15% to 20%. In the case of an individual with a negative test result, the report should include a Bayesian estimate of the posterior risk of carrying a mutation.[5]

Where genetic testing is based on linked genetic markers, the report should indicate the false-negative and false-positive rates arising from recombination between the test locus and the disease locus. This can be inferred from the known genetic distance between the loci.

In the case of some genetic diseases, the genotype-phenotype relationship varies with the mutation and the pattern of inheritance (e.g., dominant versus recessive) and the report should include an appropriate discussion of the findings relevant to the observed mutations. For example, some mutations in *CYP21* (the steroid 21-hydroxylase

gene)–such as the common gene deletion mutation–are associated with severe, classic congenital adrenal hyperplasia (an autosomal recessive disorder) whereas other mutations, such as V281L, in the same gene are associated with the late-onset form of the disease, which is characterized by milder symptoms of androgen excess in females.[7] In the case of Huntington disease (an autosomal dominant disorder), expansions of the pathogenic trinucleotide repeat in the range of 35 to 39 repeats are associated with a later age of onset than are mutations of ≥40 repeats.[9] Information on mutation-specific phenotypes, penetrance, and pattern of inheritance should be described. It is also common practice to include in reports of genetic testing a statement that genetic counseling may be appropriate for the patient and family.

Laboratories that perform genetic studies occasionally encounter families in which the laboratory findings are inconsistent with the reported paternity. These situations should be discussed with the clinician or genetic counselor to determine whether specimens were correctly labeled and the family relationships accurately reported on the requisition form. If there is a possibility of a sample mix-up, new samples should be obtained. In cases of demonstrated nonpaternity, it may not be possible to determine the risk of a genetic disease to an offspring and the report should indicate this. The issue of nonpaternity or undisclosed adoption is clearly one that has to be approached with great discretion by the genetic counselor or other professional who is responsible for communication of the test result to the patient or family.

It is not uncommon for patients, fearing discrimination, to request that genetic testing be performed without informing their health insurance companies and without having the results entered into the medical record. In such situations, the genetics results are often stored in a shadow chart maintained by the patient's physician in a private office or similar location. This practice is problematic for various reasons. First, a complete medical record may be needed in an emergency, and the absence of essential medical information may delay appropriate medical therapy. Storing portions of the record in separate locations undermines the integrity and usefulness of the medical record. In addition, as a practical matter, the reason for a clinic visit and some mention of the test result usually appears elsewhere in the medical record (e.g., in correspondence between physicians), and therefore the degree to which a test result can be truly sequestered from the formal medical record is probably limited. Also, from a legal perspective, the medical record includes all information relevant to a patient's care, even if that information is stored in an alternative location. The entire medical record should be available to authorized personnel.

The immediate resolution to these issues is to ensure that the complete medical record is secured and that hospital employees and others access only information that is needed for patient care. All employees should be made aware of policies related to confidentiality of patient records and the importance of adhering to principles of patient privacy. In the United States, this is not just an ethical requirement, but also a legal one under the Health Insurance Portability and Accountability Act of 1996 (HIPAA).[3] Respect of patient privacy should make the use of shadow records unnecessary. More global solutions to fears of genetic discrimination require introduction of legislation that forbids such discrimination, particularly in employment and insurability.[10]

Use of Analyte-Specific Reagents

In the United States, laboratory methods that involve the use of analyte-specific reagents (which include many molecular test methods) necessitate a disclaimer on test reports. The language should include the statement that "this test was developed and its performance characteristics determined by (laboratory name). It has not been cleared or approved by the U.S. Food and Drug Administration."[4] This statement is not required for tests that have been cleared by the FDA for use in clinical diagnostics. The language of the statement may be misinterpreted by some insurance payers as meaning that the test was performed for research purposes. To avoid this misperception, many laboratories include an additional statement to the effect that the test was not performed as a research test or that approval is not required by the FDA. Specific wording addressing this is recommended by the CAP molecular pathology inspection checklist.[2]

Correlation With Other Laboratory Results

For testing in areas such as molecular oncology, inherited disorders, and posttransplantation bone marrow engraftment, it is common that other testing is performed on the sample. This may include morphology studies, flow cytometry, or cytogenetic evaluation. Where possible, the results of molecular diagnostic tests should be compared with those from other tests to ensure that results are consistent, or that inconsistent results are fully investigated before a final report is issued. Such practice should be an integral component of the laboratory's quality assurance program.

Quality Assurance and Quality Improvement

Assuring the quality of reagents and test results is reviewed in this section.

Testing of New Reagents

Because of the relatively high reliance on in-house developed assays in molecular diagnostics laboratories, it is still quite common for laboratories to produce their own reagents. Careful preparation of all reagents is essential; however, certain reagents such as PCR primers and Southern blot probes are particularly critical. Commonly, these are produced by the laboratory or by commercial suppliers that may vary in the degree of process control of the reagent manufacturing. Before any reagent is placed into service, it is necessary to verify that it performs to specification. The most straightforward way to do this is by comparing the results obtained with the new reagent lot with those from a previous lot. This comparison should contain known positive and negative controls or as many of the possible genotypes as are

available. Additional validation steps can be taken: in the case of Southern blot probes that are cloned in plasmids, it may be possible to verify the identity of the probe by examining the restriction digestion pattern of the plasmid or by sequencing the cloned insert. In the case of PCR primers, the sequence of the PCR product can be determined to confirm that the expected gene sequence is being amplified. The laboratory should retain documentation on the locus, sequence, origin, restriction map, presence of polymorphisms, presence of cross-hybridizing bands, and other relevant information for each probe or primer set that it uses. Such information can be invaluable in resolving unusual or unexpected results.

Quality Control

As a matter of routine quality assessment, control specimens that test the entire preanalytic, analytic, and postanalytic process should be used. For example, in the area of microbiology or oncology testing, positive and negative control samples should be analyzed with any patient samples and taken through the extraction, amplification, and detection portions of the analysis to assure that established limits of detection and/or quantification are being met. Any amplification reaction should include a blank control that contains all reagents but not an amplifiable template as a means to identify amplicon contamination.

Laboratories that perform genetic testing for mutations should have control materials containing known mutations or wild type of alleles that are analyzed on a regular basis to confirm that the analytical method is producing accurate results; at least one sample should be included in every patient run. For certain genetic tests, where there are a limited number of known mutations, it may be possible to include both mutation and wild type of controls with each analytical run. However, many genes of interest include a large number of mutations, so that it is not always practical to run a control for each mutation with every analytical run. In such a situation, a reasonable compromise must be achieved that ensures that the analytical method can detect all mutations. This might be accomplished, for example, by testing all control samples when new lots of critical reagents are first placed in service, and thereafter by rotating a different set of mutation controls with each run. Control materials containing known mutations can be obtained from several sources. These include cell and DNA repositories, such as the one maintained by Coriel Laboratories, and synthesized control materials, such as oligonucleotides. Analytical methods that produce quantitative results e.g., for HIV-1 viral load measurement, should include appropriate calibrators and controls. Sources of calibrators and controls include commercial manufacturers and in-house developed materials.

Proficiency Testing

Although proficiency testing (PT) is discussed in Chapter 19, some additional comments regarding PT in the molecular diagnostics laboratory are necessary. The major PT program in the United States is provided by the CAP. U.S. laboratories that hold a certificate under the Clinical Laboratory Improvement Act must be enrolled in an acceptable PT program if one is available. Because of the limited number of tests that are covered in organized PT programs, it is often necessary for laboratories to perform some other means of PT. These must be performed at least semiannually. If no formal PT program exists, acceptable alternatives include participation in ungraded PT challenges, sample exchange with other laboratories performing the test, split sample analysis with another in-house method or by another technologist using the same method, testing of assayed materials, regional pools, and clinical validation by chart review or other means. Wherever possible, the PT program should cover the entire testing process. In the case of molecular diagnostics, this should include nucleic acid extraction, sample analysis, and interpretation of the results, including (if appropriate) Bayesian calculation of risk. The results of all PT challenges must be documented and reviewed by the laboratory director or designee.

SUMMARY

The design and operation of a molecular diagnostics laboratory have several unique aspects that differ from other clinical laboratories. The choice of a central facility versus discipline-specific molecular diagnostics laboratories will have a large impact on overall cost and efficiencies. In choosing a test menu, careful attention should be paid to costs, reimbursement, expected volumes, turnaround times, and the expertise required of personnel. The use of target amplification methods requires careful attention to laboratory design and workflow.

Operational details that are specific to a molecular diagnostics laboratory include regulatory issues related to genetic information that may vary between jurisdictions, personnel qualifications, and availability, and the ability to report genetic results that are based on Bayesian calculations. Use of appropriate quality control materials and participation in a proficiency testing program that challenges all phases of the analytical process are essential for successful operation of a molecular diagnostics laboratory.

CHAPTER 39

Molecular Genetics and Diagnosis of Hematopoietic Neoplasms

Kojo S.J. Elenitoba-Johnson, M.D.

The hematopoietic neoplasms are a diverse group of malignancies that traditionally have been diagnosed by use of a variety of ancillary techniques. Important advances over the last few decades have elucidated the biological bases for the development of these diseases. The hematopoietic malignancies include the lymphomas, leukemias, and plasma cell dyscrasias. These diseases represent neoplastic proliferations of the hematopoietic system and are characterized by monoclonality, clonal progression, clonal dominance, and suppression of normal clones.

The *leukemias* are malignant neoplasms that are primarily bone marrow– and peripheral blood–based. Thus the diagnostic material in these cases is typically obtained from the bone marrow or the peripheral blood. The leukemias are classified according to a putative lineage commitment or stage of differentiation (e.g., myeloid, myelomonocytic, lymphoblastic, lymphoid, etc.) and clinicopathological characteristics, such as disease onset and aggressiveness of clinical course (acute versus chronic). Simply stated, the tumor cells in acute leukemias consist mainly of immature or blast cells with limited differentiation. By comparison, a significant proportion of the neoplastic cells in the chronic leukemias are mature and differentiated.

The *lymphomas* are neoplasms of B-, T- or natural killer cells, and characteristically present as tumorous enlargements of peripheral lymphoid or extranodal tissues. As with the leukemias, the lymphomas are subclassified into distinct clinicopathological entities based on lineage, cell of origin and/or putative normal counterpart, and degree of differentiation. Despite their designation as primarily tissue-based neoplasms, malignant lymphomas may involve the bone marrow or peripheral blood. Conversely, leukemic proliferations may occur in tissue as extramedullary tumorlike nodules or masses (extramedullary myeloid tumors) or in the peripheral blood.

This chapter reviews the diagnostic techniques that are routinely used in molecular diagnostic laboratories for the detection and quantification of the distinctive molecular genetic abnormalities that are characteristic of several hematopoietic neoplasms. Identification of the fundamental aberrations involved in the genesis of lymphomas and leukemias has permitted the development of tumor-specific therapeutic interventions and molecular tests, which serve as important adjuncts in the specific diagnosis, choice of therapy, monitoring, and overall management of patients affected with hematological malignancies. This chapter is by no means an exhaustive listing of these tests, but an attempt has been made to illustrate the utility of the more common techniques with a prototypical example in each case. Where relevant, some detail is provided into the physiology or pathogenesis of specific neoplasms that provides insights into the molecular basis for the particular assay design. The most commonly performed molecular tests for the evaluation of hematopoietic neoplasms are tests for rearrangement of antigen-receptor genes and analyses for recurrent chromosomal translocations. In many cases the genetic markers are exploited as unique markers for specific categories of hematological neoplasia, and hence receive the most attention in this chapter.

ANTIGEN-RECEPTOR GENE REARRANGEMENTS FOR DETERMINATION OF CLONALITY

The histological features that distinguish benign reactive lymphocytic proliferations from malignant populations can be subtle and somewhat subjective. The introduction of molecular biological techniques into diagnostic pathology has refined lymphoma diagnostics and classification. B- and T-lymphocytes exhibit the unique property of rearrangement of the immunoglobulin (Ig) and T-cell receptor (TCR) genes, respectively. The immunoglobulin and T-cell receptor genes encode the amino acid sequences of the polypeptides that constitute the corresponding antigen receptor. The antigen-receptor molecules mediate antigen recognition and are responsible for the specificity of the normal immune response. B-lymphocytes are the mediators of humoral response and produce immunoglobulins, while the T-lymphocytes are the mediators of the cellular response. Because each reactive lymphocyte carries a unique antigen-receptor gene sequence, identification of clonal populations arising from a parent malignant lymphocyte becomes feasible since the malignant population is characteristically monoclonal. Tests for monoclonality were originally developed using the Southern blotting hybridization (SBH) methodology, which remains the gold standard for specificity for detection of clonality throughout a broad range of lymphoid malignancies (Table 39-1). More recently, SBH has been complemented by polymerase chain reaction (PCR)–based strategies.

Molecular Genetic Basis for Immunoglobulin-Gene Rearrangements

Humoral immunity is achieved by the cognitive and effector functions provided by B-lymphocytes. Immunoglobulins (Ig) are produced exclusively by B-lymphocytes, and constitute the hallmark of the humoral response. Ig molecules are heterodimeric polypeptides consisting of two identical 50 to 70 kD heavy chains associated with two identical light chains (κ or λ) of approximately 23 kD. The Ig chains are linked by noncovalent forces and interchain disulfide bridges, and together form a bilaterally symmetrical structure. The heavy and light chain proteins encoded by their corresponding genes consist of a tandem series of homologous segments, comprising approximately 110 amino acid residues. These segments undergo folding into 12 kD domains with single intrachain disulfide bridges. Heavy chains contain one variable (V) and three constant (C) domains, while light chains contain one N-terminal V and one C domain. In both heavy and light chains, the V domain consists of four relatively invariable framework regions of 15 to 30 amino acids separated by three 9- to 12-amino acid–long hypervariable or complementarity determining regions (CDR). In both heavy and light chains, the CDR3 region is the farthest away from the N-terminus and exhibits the greatest sequence variability among the three CDRs. The C-terminal region of secreted Ig molecules binds to complement components and Fc receptors. The genes encoding the Ig proteins are the target for DNA-based studies for clonality assessment.

The organization of Ig genes in the germline is fundamentally similar in all species studied. Genes encoding the two light chains, κ and λ, and the locus containing the various heavy chain genes are located on different chromosomes. To generate the large number of antibody molecules necessary, B-cells have evolved a unique strategy that involves recombination of germline-encoded immunoglobulin gene segments and a somatic hypermutation mechanism that further diversifies the reactivities of the rearranged antigen-receptor molecules.[114] The three immunoglobulin gene loci—for IgH, Igκ, and Igλ—are located at chromosomes 14q32, 2p12, and 22q11, respectively. In the germline configuration, all antigen-receptor genes consist of discontinuous DNA segments, which are referred to as variable (V), diversity (D), joining (J), and constant (C) regions. While both the Ig heavy and light chain genes contain V, J, and C regions, only the IgH genes contain D regions (Figure 39-1). The IgH gene contains approximately 51 V_H segments, 27 D_H segments, 9 J_H segments, and 11 C_H genes. The IgH V_H segment genes can be categorized into seven families based on the relatedness of the DNA sequences.

The ability of the immunoglobulin genes to undergo recombination in a manner analogous to shuffling of cards affords the capacity to achieve an enormous primary Ig repertoire of 10^9 sequences (Figure 39-2). The region coding

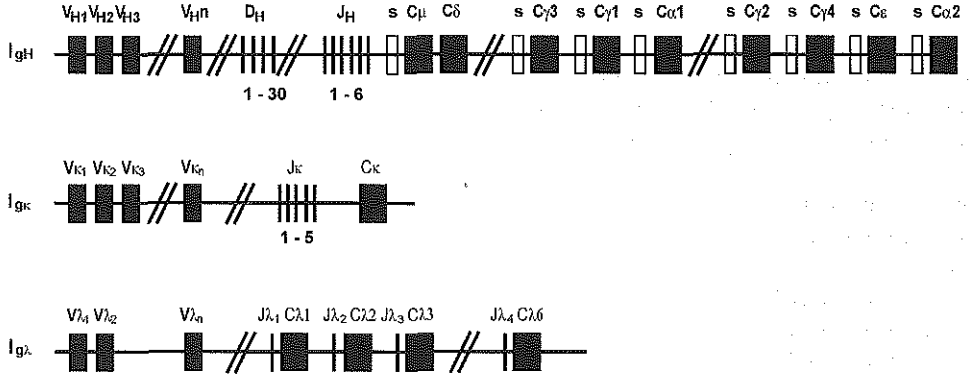

Figure 39-1 Schematic representation of the germline configurations of the antigen-receptor gene loci. Immunoglobulin heavy chain (IgH), immunoglobulin kappa (Igκ), and lambda (Igλ) light chains. Each gene comprises several variable (V), joining (J), and constant (C) segments. Note that the IgH gene contains diversity (D) gene segments. Switch regions are indicated by S.

Table 39-1 Detection Frequency of Antigen-Receptor Gene Rearrangements by Southern Blot Analysis

	Cases With Antigen-Receptor Gene Rearrangement (%)					
	Immunoglobulin Genes			T-Cell Receptor Genes		
	IgH	Igκ	Igλ	TCRβ	TCRγ	TCRδ
B-cell Neoplasms						
Precursor B-cell acute lymphoblastic leukemia/lymphoma	100	40-50	20-25	20-30	50-60	70-80
Chronic lymphocytic leukemia/ small lymphocytic lymphoma	10	100	30	<10	<10	<10
Prolymphocytic leukemia	100	100	30	Rare	Rare	NA
Hairy cell leukemia/variant	100	100	30-50	Rare	NA	NA
Lymphoplasmacytic lymphoma/ immunocytoma	100	100	30	Rare	NA	NA
Marginal zone B-cell lymphoma						
Low-grade, B-cell lymphoma of mucosa-associated lymphoid tissue	100	100	30	<10	Rare	NA
Splenic marginal zone lymphoma	100	100	30	0	NA	NA
Mantle-cell lymphoma	100	100	50	Rare	NA	NA
Follicular lymphoma	100	100	30	<10	<10	<10

Mycosis fungoides/Sézary syndrome	0	0	0	70-80	70-80	>90

for human Ig C contains 11 C region segments, which define 9 functional immunoglobulin classes and subclasses (IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE). The C region genes are initially uninvolved in the rearrangement process but are subsequently juxtaposed to the VDJ complex during RNA splicing. Incorporation of the C regions into the rearranged VDJ recombination permits *class switching* (i.e., the specific V(D)J rearrangement can be expressed as an IgG, IgA, or other Ig classes). Following the formation of a productive IgH rearrangement, the light chain loci undergo a similar recombination process involving the joining of V to J segments, since there are no D segments present in the light chain loci.[26]

The Igκ light chain gene is located on chromosome 2p11-13, and contains approximately 76 Vκ genes, 5 Jκ segments, and 1 Cκ gene. There is a κ-deleting sequence (element)

present 3′ to the Cκ region. In Igλ-expressing B-cells in which the Igκ genes are not productively rearranged, the κ-deleting element undergoes rearrangement such that the Cκ locus is deleted. The Igλ light chain is situated on chromosome 22q11, and consists of 70-71 Vλ genes with 7-11 Jλ and 7-11 Cλ genes arranged in tandem. The Cλ locus is polymorphic and may be present in one to nine copies per allele in different individuals. The hierarchy of the rearrangement events is such that both alleles of the heavy chain rearrange before the light chain genes; the kappa (κ) light chain locus usually is productively rearranged before the lambda light chain genes. Thus the immunoglobulin lambda (λ) light chain gene is not favored for clonality analysis because it frequently rearranges after the kappa light chain gene. In addition, because the majority of clonal rearrangements of the immunoglobulin heavy chain gene can be detected in up to 95% of clonal processes, it has become customary to perform only Southern blot analysis for the IgH locus in many laboratories.

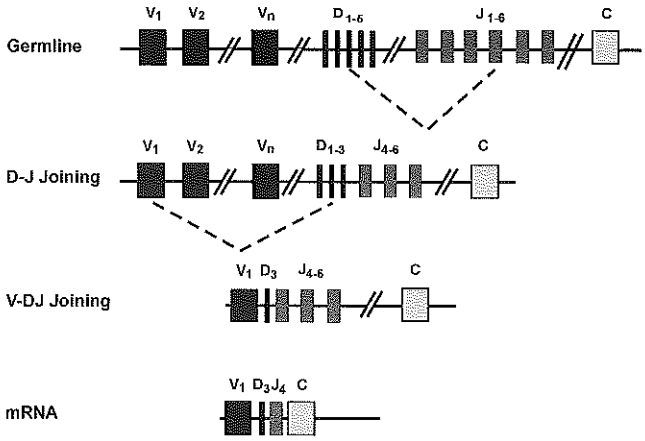

Figure 39-2 Schematic representation of antigen-receptor gene rearrangement mechanism using the IgH chain locus as a model. There is an initial DJ joining in a partial/incomplete recombination, followed by a VDJ joining to complete the rearrangement. The C regions are included at the mRNA level via RNA splicing to form a V(D)JC transcript.

Molecular Genetic Basis for T-Cell Receptor Gene Rearrangements

A process similar to that described for the Ig genes occurs in the TCR genes, with the notable exception of the absence of a somatic hypermutation mechanism in TCR gene rearrangements. The developmental hierarchy of TCR genes is such that the TCR-δ gene is the first to rearrange, followed by the TCRγ, TCRβ, and then the TCRα genes.[24] The TCR-δ gene is located on chromosome 14q11, and contains up to six Vδ segments, only two or three Dδ segments, and three Jδ segments. It is located within the TCR-α gene, immediately 3′ to the last TCR-Vα gene and 5′ to the TCR-Jα segments. This location is important since productive rearrangements of the TCRδ gene lead to expression of the γ/δ TCR. In the event that the TCRδ rearrangement is nonproductive, Vα to Jα rearrangements obligatorily require that the TCRδ be deleted.

As previously indicated, the TCRδ gene (Figure 39-3) is located on band 14q11, flanks the TCRα gene on either side, and contains several Vα segments. An extensive J region comprises up to 50 Jα genes and 1 Cα locus. By virtue of the architectural disposition of the TCRα and δ loci, rearrangement of a Vα segment to a Jα segment typically leads to deletion of the intervening TCRδ loci. T-cells undergoing such rearrangements may then go on to express the TCR-α/β protein. The TCRβ gene is located on band 7q34 and contains 75 to 100 Vβ segments, flanked at the 3′ end by two Dβ, Jβ, and Cβ regions. For each region, there is one Dβ segment, with six or seven Jβ segments, and one Cβ segment. Rearrangements may occur within or between segments (e.g., Vβ1 to Jβ1 or Vβ2 to Jβ1). There is extensive sequence homology between the Cβ1 and Cβ2 segments. This phenomenon is exploited in the use of a consensus Cβ probe when Southern blotting of the TCR genes is used for clonality assessment. The TCRγ gene is located on band 7q15, and contains about 12-15 Vγ segments and 2 Jγ genes.[22] The

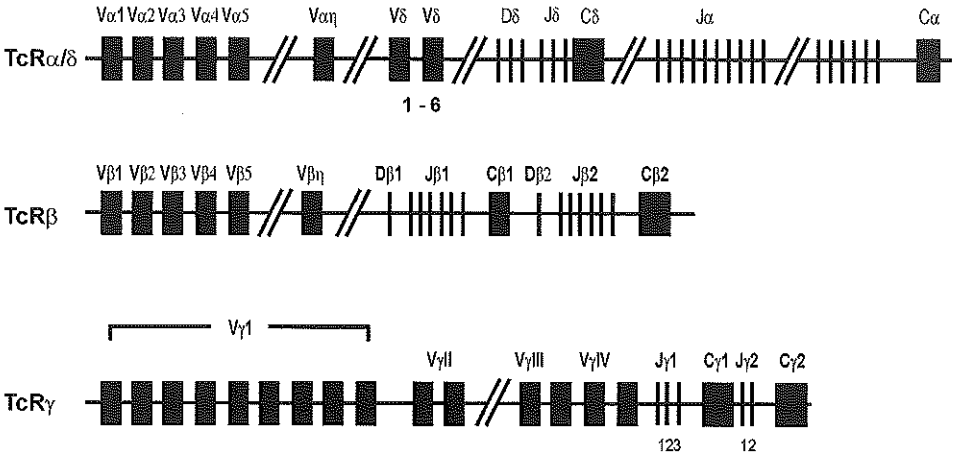

Figure 39-3 T-cell receptor (TCR) genes consist of α/δ-, β-, and γ-chain genes. The architectural configurations are similar to that of the Ig loci. Note that only the TCRβ- and δ- genes contain diversity (D) regions.

simple structure of the architecture of this gene favors its use as a target for TCR receptor PCR, whereas consensus primers are designed to encompass the relatively few Vγ and the Jγ genes.

Southern Blot Hybridization Analysis for Antigen-Receptor (Ig or TCR) Gene Rearrangements

In this procedure, high-quality total cellular DNA extracted from a fresh or flash-frozen specimen is subjected to digestion by bacterial restriction endonucleases, which produce DNA fragments encompassing the Ig or TCR gene region segments to be interrogated (Figures 39-4 and 39-5). The enzyme-digested ("restricted") DNA from each enzyme is subjected to gel electrophoresis and transferred by blotting and immobilized on a membrane. A labeled-probe complementary to the Ig J region segment is hybridized to the membrane. Clonal rearrangements are recognized by the identification of one or two novel rearranged bands that are distinct from the germline pattern obtained with a benign sample or placental DNA. One or two novel rearranged (nongermline) bands may be identifiable depending on whether there is a clonal monoallelic or biallelic rearrangement (Figure 39-6).

Materials suitable for Southern blot analysis include fresh tissue or aspiration biopsy material, as long as sufficient cellular material can be obtained from the specimen of interest. Ethanol-fixed tissue can also be used. However,

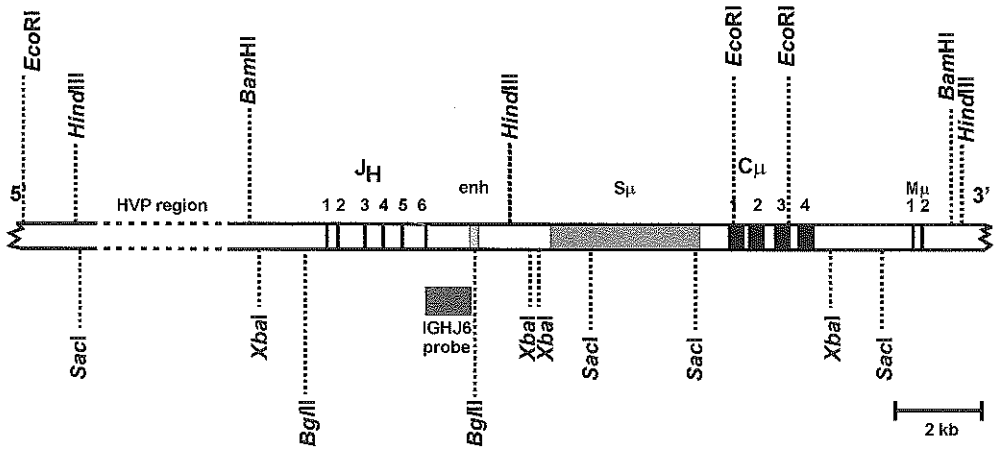

Figure 39-4 Restriction map of the IgH chain locus. The sites of the enzyme restriction sites determine the sizes of the fragments that are visualized using the IgHJ6 probe as illustrated (e.g., BamHI, Xbal, and BglII enzymes yield 16 kb, 6.2 kb, and 3.8 kb fragments, respectively). Restriction patterns different from the germline patterns are indicative of a novel rearrangement event.

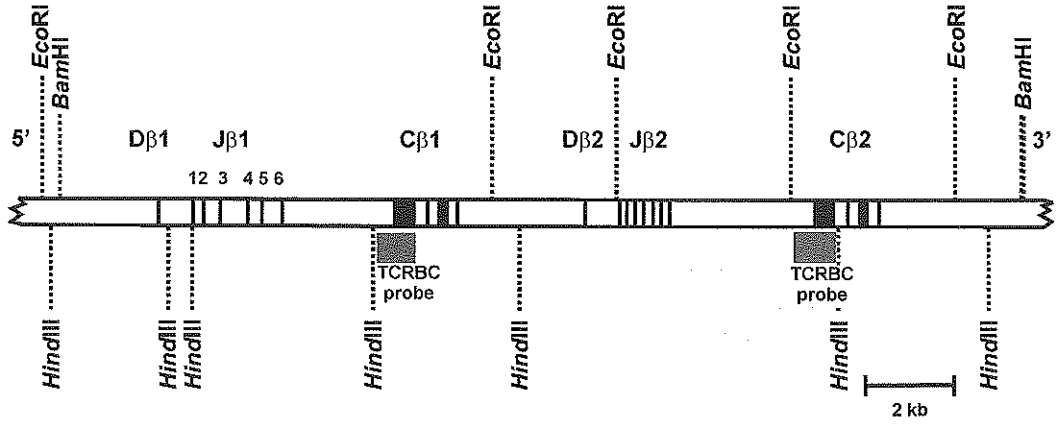

Figure 39-5 Restriction map of the TCRβ chain locus. The probe is complementary to the TCRβ constant region. There is extensive sequence homology between the Cβ1 and Cβ2 segments. Thus the Cβ probe hybridizes to both the Cβ1 and Cβ2 segments, thereby resulting in two germline band signals for all enzymes depicted except BamHI. The EcoRI site located between the Cβ1 and Jβ2 segments is notoriously resistant to digestion and may yield a partial digest with a band of 8.0 kb in size.

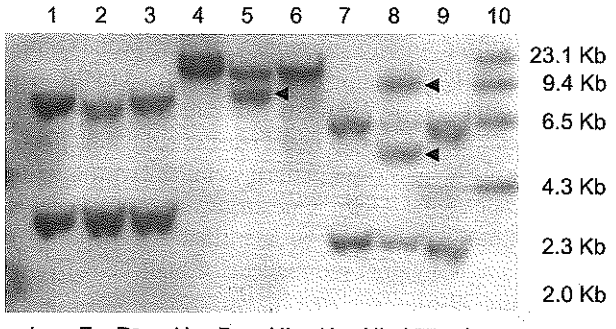

Figure 39-6 Southern blot hybridization analysis for clonal rearrangements of the TCRβ chain locus. DNA samples extracted from two different patients with a suspected diagnosis of T-cell lymphoma are assessed. Lanes 1 to 3 represent the EcoRI digests. Lanes 4 to 6 show the BamHI digests, and lanes 7 to 9 demonstrate the HindIII digests from both samples run side by side. Lane 10 shows the DNA size marker. Lanes 1, 4, and 7 show the restriction patterns in the germline control (placenta) using the EcoRI, BamHI, and HindIII enzymes, respectively. DNA from patient 1 (Lanes 2, 5, and 8) shows a germline pattern using EcoRI, but novel rearrangements (arrowheads) using BamHI and HindIII. Patient 2 (lanes 3, 6, and 9) shows a germline pattern in all three enzyme digests. Accordingly, sample 1 is scored as showing evidence for a monoclonal T-cell population, and sample 2 is scored as showing evidence of a polyclonal T-cell population.

formalin-fixed tissue yields DNA of insufficient quality to permit reliable Southern blotting because of cross-linking of proteins to DNA. A Southern blot hybridization assay using three enzymes requires approximately 1.5×10^7 cells (approximately 15 μg of intact total cellular DNA). Hypothetically, all of the antigen-receptor genes could be used as potential targets for the assessment of clonality, but only the immunoglobulin heavy and light chain and the TCR beta chain loci have gained widespread use. The T-cell TCRα locus is impractical, because it contains several J segments that are distributed widely, and thus would pose practical challenges in the optimization of assays for multiple probes. Evaluation of the TCRγ and δ loci is also not favored because they have only a limited number of V segments such that even reactive T-cell populations may yield confusing nongermline bands.

The diagnostic hallmark of a clonal population is the presence of a nongermline novel rearranged band (see Figure 39-6); but nongermline bands do not always indicate monoclonality. Single nucleotide polymorphisms (SNPs) may create or abolish restriction enzyme recognition sites thus yielding novel restriction banding patterns. In this scenario, digestion with a different restriction endonuclease would yield a germline configuration. The potential of SNPs to confound the interpretation of Southern blot studies justifies testing with up to three or more enzymes for the unequivocal assignment of monoclonality. Incomplete digestion by a restriction enzyme can also result in a nongermline band that does not indicate monoclonality. This is typically evident in the control sample (placental DNA) and invalidates the significance of any such band in the test sample.

Clonal rearrangements of either the Ig or TCR genes have also been used to ascertain the lineage of hematological neoplasms that do not express B- or T-cell specific markers. Intuitively, clonal rearrangements of the Ig genes would indicate B-cell processes, and clonal rearrangements of the TCR genes would indicate T-cell processes. However, some malignant lymphomas (notably lymphoblastic) and leukemias (especially acute leukemias) may demonstrate both Ig and TCR rearrangements. Further, up to 20% of acute myeloid leukemias (AMLs) may demonstrate rearrangements of either the Ig or TCR genes.[19,51,60] Hence, lineage is best assigned using a combination of immunophenotypic and molecular studies.

Polymerase Chain Reaction Analysis of Antigen-Receptor Gene Rearrangements

Although analysis by SBH for detection of antigen-receptor gene rearrangements is recognized as the "gold standard" for the assessment of clonality, PCR-based assays have become the mainstay for the detection of rearrangements of the Ig and TCR genes in many molecular diagnostic laboratories. SBH is not only labor-intensive and time-consuming, but it requires a substantial quantity of "intact" DNA (with full-length or nearly full-length copies of the gene or genes of interest), making it less amenable to use for specimens with suboptimal DNA quality (as is the case with fixed paraffin-embedded tissue samples). PCR is well suited for such specimens, which constitute the majority of samples analyzed in the clinical laboratory.

The application of PCR for the identification of clonality entails the use of consensus V-region and J-region primers and in vitro amplification of DNA across the V(D)J junction followed by evaluation of the PCR products by gel electrophoresis or other methods for analysis of the uniformity of PCR-generated fragments. In the germline configuration, these V- and J-region segments are located several kilobases apart and would not be amplifiable. However, the V(D)J recombination brings the VDJ segments into close proximity and thereby permits amplification of products that are less than 80 to 350 bases depending on the primers used. The V-region primers are typically designed to be complementary to the relatively conserved framework regions (I, II, or III), and the J-region primer is typically complementary to consensus sequences present across all six J regions in the immunoglobulin heavy chain gene. Similar strategies exist for the light chain genes as well, but the rate of detection of clonal rearrangements is lower and hence the IgH-PCR is favored. Use of framework III consensus primers provides the highest rate of detection, but can be complemented with increased diagnostic sensitivity afforded by the inclusion of framework II and/or framework I primer-mediated IgH-PCR for clonality. Among the T-cell assays, the TCRγ-PCR is the most informative. In these assays, monoclonal populations yield one or two dominant bands (Figure 39-7). Poly-

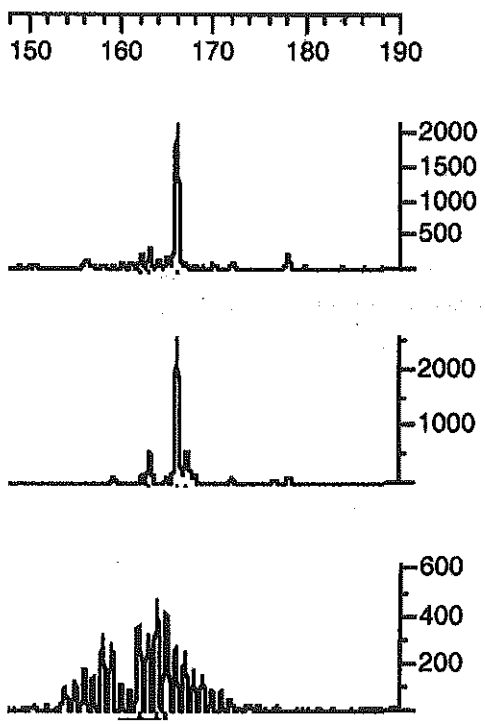

Figure 39-7 Polymerase chain reaction (PCR) analysis for clonal rearrangements of the antigen-receptor gene loci. PCR analysis of the TCR γ-chain locus is shown. The upper and middle panels show duplicate assays with monoclonal capillary electrophoretic peaks of identical size (~166 bp) in both replicates. The bottom panel shows a polyclonal pattern.

clonal cells, each of which carries a unique rearrangement with slightly different band sizes, demonstrate a ladder or smear pattern on gel electrophoresis.[67,109] Following completion of PCR, the PCR products are analyzed by gel electrophoresis.[34,113] The PCR products are most commonly visualized by ultraviolet transillumination of ethidium bromide–stained gels. Agarose and polyacrylamide gels are most commonly used for resolution of PCR products. Agarose gels have the advantages of being relatively inexpensive and easy to make, but they provide inferior resolution of PCR products, such that products of similar size can be difficult to distinguish. Polyacrylamide gels offer significantly better product resolution and can be configured to reliably discriminate bands differing in size by as little as three bases. This is often highly useful in the assessment of PCR products for antigen-receptor gene rearrangement assays. Even further resolution may be achieved by supplementation of size fractionation with additional parameters. Denaturing gradient gel electrophoresis and temperature-gradient gel electrophoresis achieve finer resolution of PCR products by exploiting the sequence-specific and melting characteristics of double-stranded DNA.[47] The incorporation of denaturants, such as formamide or urea in gradient gels, or modulation of the temperature can further increase resolution based on the melting temperature (Tm) of the DNA sequence rather than on size. Radioisotopic detection is an alternative to ethidium bromide detection. The PCR primers could be labeled with radioisotopes, the PCR products analyzed by electrophoresis, and the PCR products visualized by autoradiography. Ultraviolet transillumination of ethidium bromide–stained gels is more popular than radioisotope-based methods, because it is easier to perform and poses fewer hazards with regard to handling and disposal of radioactive wastes. A successful PCR exhibits PCR products in the expected size range, appropriate results in the positive and negative controls, and absence of bands in the template-free (H_2O) control.

PCR-based clonality assays are less sensitive in detecting all of the possible clonal rearrangements than is SBH analysis, which approaches 100% if sufficient restriction enzymes and a variety of probes are used. Depending on the assay and the lymphoid neoplasm tested, PCR-based clonality studies may show false-negative rates of 10% to 40% when compared with SBH. A reason frequently cited to explain the high false-negative rate for PCR is that, in contrast to SBH, PCR does not detect partial DJ rearrangements, wherein the V- and J-region genes are not approximated to one another and are too distant for conventional PCR to generate an amplification product. Secondly, the consensus primers in PCR tests are incapable of hybridizing to all of the different V regions, any one of which could be potentially present in any one neoplasm. Of particular importance to the Ig genes, somatic mutations occurring within the Ig V-region genes also result in decreased ability for the consensus V-region primers to anneal optimally to the V-region genes in the template DNA. Thus lymphoid neoplasias such as follicular lymphoma with a high somatic hypermutation rate yield lower positive rates by PCR-based Ig clonality tests.[103,104] Most of these difficulties can be overcome by use of multiple primer sets. In the event of a negative PCR result, SBH analysis may be performed if sufficient high-quality genomic DNA is available. The main drawback for PCR is the marked propensity for contamination. Thus various strategies for contamination control, such as maintaining separate DNA extraction and amplification rooms, use of laminar flow hoods, and incorporation of uracil DNA glycosylase into PCR, generally should be employed to prevent contamination problems.

The ability to detect a rare, aberrant DNA species in a background of normal DNA (often referred to as "sensitivity" of the PCR-based tests) is dependent on the particular application. For antigen-receptor gene rearrangement studies, PCR can detect a monoclonal population in a background of 10^2 to 10^3 polyclonal cells of the same phenotype (B- or T-cells). By comparison, PCR can detect one cell harboring a chromosomal translocation within a background of 10^5 to 10^6 cells negative for the translocation.[76]

LYMPHOMA-SPECIFIC RECURRENT CHROMOSOMAL TRANSLOCATIONS

The immunoglobulin gene rearrangement process, which is integral to the normal development of B-cells and the elab-

oration of an appropriate immune response, is susceptible to abnormal translocation of foreign genes. Translocation of these genes is associated with their deregulation, which is integral to the development of lymphoid neoplasia. A translocation typically involves the transfer of a piece of one chromosome to a different chromosome. Nonrandom chromosomal translocations are frequently observed in hematological neoplasia and in many cases are characteristic of a specific type of leukemia or lymphoma.

The translocations typically result in one of two genetic consequences.

1. The translocation may juxtapose an oncogene and an antigen-receptor gene, leading to dysregulated expression of the oncogene and increased concentration of the oncoprotein. This is the mechanism most frequently seen in malignant lymphomas, and is exemplified by the t(14;18)(q32;q21) that is characteristic of follicular lymphoma. The translocation juxtaposes the *bcl-2* gene (18q21) and the IgH gene (14q32), leading to overexpression of the *bcl-2* gene and increased *bcl-2* mRNA and protein.[116]
2. Alternatively the chromosomal translocation leads to the in-frame juxtaposition of two different genes, with resultant creation of a novel chimeric gene. This mechanism is most commonly observed in the leukemias and less commonly in malignant lymphomas. In the t(2;5)(2p23;q35) seen in anaplastic large cell lymphoma, an abnormal fusion gene (*NPM-ALK*) is formed and is central to pathogenesis.[80] Similarly, a t(11;18)(q21;q21) is seen in a subset of extranodal, marginal-zone B-cell lymphomas of mucosa-associated lymphoid tissue. This translocation forms an abnormal *API-MLT1* chimeric fusion that is implicated in the molecular pathogenesis of the malignant lymphoma.[27]

Reverse-transcription-PCR is well suited for the diagnostic detection of such chimeric fusions, because the fusion product is often within the size range that can be amplified by conventional PCR. Secondly, many of the translocation breakpoints are widely dispersed and not clustered. If DNA were to be considered as the template for such PCR, it would best be performed as a long-distance (LD) PCR protocol. LD PCR protocols, however, are unsuitable for many types of clinical samples, such as paraffin-embedded material, that characteristically do not contain high-quality, intact genomic DNA.

A list of the common chromosomal translocations, the participating genes, and the associated lymphomas is provided in Table 39-2.

Southern Blot Hybridization Analysis for the Detection of Chromosomal Translocations

SBH analysis is an excellent method for the detection of chromosomal translocations. A sequence-specific probe to the gene of interest is used for SBH analysis as described for the antigen-receptor genes. Detection of a pattern in which bands of different sizes than are seen in the germline configuration of the gene of interest would suggest the presence of a translocation. It should be noted that this method does not identify the translocation partner of the gene of interest. As with the antigen-receptor gene rearrangement, studies by SBH single nucleotide polymorphisms at enzyme restriction sites may result in nongermline patterns that may be misinterpreted as translocations. In this scenario, use of a different restriction enzyme will correctly show the gene locus to be of germline size. The labor-intensive nature of SBH and the requirement for high-quality DNA have diminished its popularity for routine detection of chromosomal translocations in the clinical laboratory. PCR continues to gain increasing use for the routine detection of recurrent chromosomal translocations.

Polymerase Chain Reaction Analysis for Detection of Chromosomal Translocations

The polymerase chain reaction is a methodology that is very well suited for the analysis of chromosomal translocations, particularly when the translocation breakpoints are clustered and the sequences flanking the translocation breakpoints are well characterized.

t(14;18)(q32;21)—*BCL-2*/JH Aberration

The t(14;18)(q32;21) that is characteristic of follicular lymphoma exemplifies the utility of PCR in the detection of a chromosomal translocation that is characteristic of a specific form of non-Hodgkin lymphoma. The t(14;18) is a balanced reciprocal translocation involving the *BCL-2* gene (18q21) and the IgH locus (14q32). The *BCL-2* gene consists of three exons and two introns.[106] There are up to four different regions on 18q21 where the breakpoints are frequently located. The 18q21 breakpoints in the majority of translocations are clustered in the *major breakpoint cluster* region (MBR). The MBR is a 150 bp sequence located within the 3′-untranslated region of exon 3 of the *BCL-2* gene and harbors approximately 60% of the breakpoints found in follicular lymphoma.[115,124] Another 20% of follicular lymphomas harbor t(14;18) aberrations in which the breakpoint is located at the *minor cluster* region, which is located 30 kb further 3′ to the *BCL-2* gene. An additional cluster of breakpoints located at the *variant cluster region* located 5′ upstream to the *BCL-2* gene harbors approximately 5% of the breakpoints found in follicular lymphoma (Figure 39-8).[95] More an *intermediate cluster region* (ICR) has been described with additional 18q21 breakpoints associated with follicular lymphoma.[1] Although initial studies comparing conventional cytogenetics, Southern blot, and PCR-based methods for detection of the t(14;18) (not including the ICR) have shown that 86% of the cases were identified by Southern blotting and 75% by PCR,[57] the inclusion of PCR assays targeting the ICR improves the detection rate for the t(14;18) by PCR.[1] Figure 39-9 (Color Plate 2) shows fluorescence in situ hybridization (FISH) analysis demonstrating the t(14;18) in a sample that tested negative by

PCR. An important caveat to note is that the t(14;18) has been detected in benign tonsils, in reactive lymph nodes,[5,71] and in the peripheral blood of normal blood donors.

t(11;14)(q13;32)—*BCL-1*/JH Aberration

The t(11;14)(q13;32) abnormality is characteristic of mantle cell lymphoma,[70,123] but rare in other types of malignant lymphoma. This translocation juxtaposes the *BCL-1* locus on 11q13 with the immunoglobulin heavy chain gene enhancer locus at 14q32.[117] Structurally, there are multiple breakpoints on chromosome 11. The most frequently involved location on 11q13 is the major translocation cluster (MTC) region, which is located 110 kb 5′ to the *BCL-1* locus.[117] Other breakpoints occurring within minor translocation cluster regions have also been described 3′ to the major translocation cluster but 5′ to the *BCL-1* locus (Figure 39-10).[94] The *BCL-1* gene consists of five exons covering a genomic distance of approximately 15 kb.[81] The gene encodes cyclin D1, which regulates cellular transition from G1 to S phase. Despite the diversity of the breakpoints flanking the *BCL-1* gene, the t(11;14) does not lead to disruption of the coding region of the *BCL-1* gene. Consequently, the expression of cyclin D1 is qualitatively normal, but quantitatively increased. One of the practical consequences of the multiple breakpoints in mantle cell lymphoma is that approximately 70% of cases of mantle cell lymphoma can be demonstrated to harbor the t(11;14) by Southern blotting analysis using multiple probes for detection of the various breakpoints.[126] By comparison, most published PCR protocols only detect approximately 40% of t(11;14) anomalies in mantle cell lymphoma (Figure 39-10), and the majority of these are clustered in the MTC.[126] This is in notable contrast to DNA fiber FISH, which reportedly may detect up to 95% of t(11;14) aberrations, making FISH the most sensitive method for detection of this abnormality.[118]

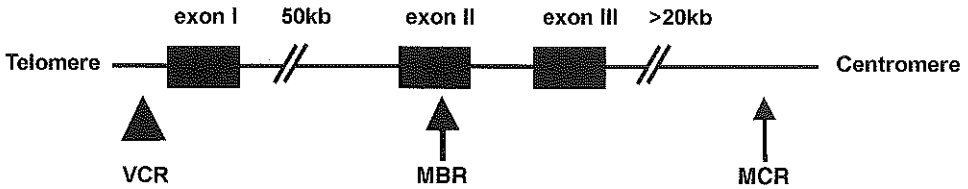

Figure 39-8 Schematic representation of the organization of the *BCL-2* gene and most frequent breakpoints on chromosome 18q21 involved in the t(14;18). The *BCL-2* exons are represented as rectangles. MBR represents the major breakpoint cluster region where approximately 50% to 60% of the breakpoints occur. MCR represents the minor breakpoint cluster region where 20% to 25% of the breakpoints may be found. VCR represents the variant cluster region where 5% to 20% of the breakpoints may be found.

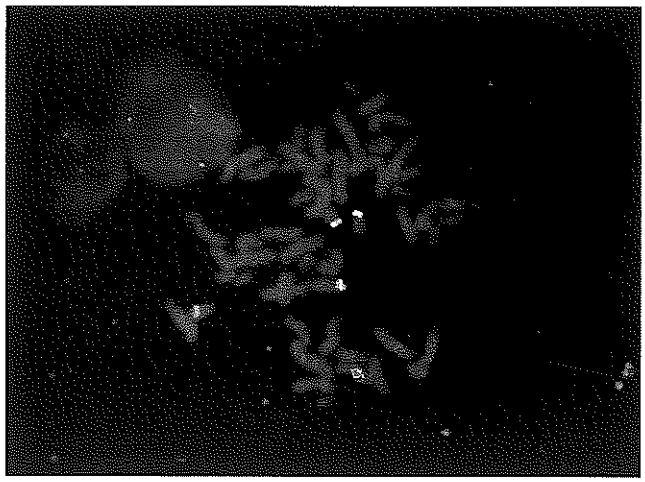

Figure 39-9 Fluorescence in situ hybridization for the t(14;18) anomaly on metaphase spreads of a case of follicular lymphoma. The immunoglobulin heavy chain sequences on 14q32 *(red)* when juxtaposed to the *bcl-2* sequences on 18q21 *(green)* yield a yellow fusion signal indicative of the presence of the t(14;18). (See Color Plate 2.)

MOLECULAR GENETICS OF LEUKEMIAS

As indicated previously, human leukemias are characterized by recurrent genetic abnormalities that can be used as genetic markers of the specific leukemia. The genetic abnormalities are most often recurrent chromosomal translocations, which result in chimeric fusions leading either to a differentiation block or enhancement of proliferation. The chronic leukemias of myeloid derived cells are characterized by constitutive activation of tyrosine kinases whose primary effect is to confer an excessive proliferative signal and an increased survival advantage. An example of this is the t(9;22), which results in the *BCR-ABL* chimeric fusion that is characteristic of chronic myelogenous leukemia (CML). Inhibition of the activated tyrosine kinase is a bona fide therapeutic option as has been demonstrated with imatinib mesylate (Gleevec) in CML. By comparison, the chromosomal translocations in the acute myeloid leukemias typically result in loss-of-function aberrations within transcription factors that lead to maturational arrest or differentiation blocks at early stages of hematopoietic development. The preponderance of evidence suggests that the genetic aberrations leading to maturational arrest in the acute myeloid leukemias are by themselves insufficient to cause leukemia. However, the concomitant occurrence of cooperating mutations in the *RAS* and the tyrosine kinase genes *FLT3* and *C-KIT* permits progression to a frank leukemia. In either case, the presence of the genetic aberrations provides a target for disease detection, monitoring, and potential gene-specific therapy. A comprehensive list of translocations and the fusions in acute leukemias is in Table 39-3 with French-American-British classification designations. The most frequently employed technique for the detection of the chimeric transcripts in the molecular laboratory is RT-PCR. In addition, the prevalence of specific genetic mutations often requires that screening for such mutations be performed in the diagnostic laboratory. While it is recognized that the definitive method for the detection of the point mutations is sequencing, a variety of techniques may be used for screening for the presence of point mutations (e.g., single-strand conformation polymorphism analysis,[86,111] denaturation gradient gel electrophoresis,[12] or fluorescence real-time PCR-based melting curve analysis).[35]

Acute Myeloid Leukemias

The translocations that occur in the acute myeloid leukemias (AML) target transcription factors or transcriptional co-activators. The transcription factors are involved in the differentiation of the hematopoietic cells, and disruption of their normal function by the translocation leads to developmental arrest and maturational block at immature stages of differentiation. The targeted transcription factors include the retinoic acid receptor alpha (RARα) in acute promyelocytic leukemia and several members of the core binding factor (CBF) complex. CBF is a transcription factor that consists of heterodimers, including a DNA-binding component known as *AML1* (*RUNX1/CBFA2/PEBP2A*), and a subunit CBFβ that activates the transcription of *AML1*. CBF is targeted in the t(8;21)[39] aberration, which results in the AML/*ETO* fusion that is characteristic of AML with differentiation (AML FAB-M2). CBF is similarly targeted in the inv(16), which leads to the CBFβ/SMMHC found in a subset of AML patients.[72] The multilineage importance of CBF is manifest in a subset of precursor B-cell acute lymphoblastic leukemias, where it is targeted in the t(12;21) that leads to

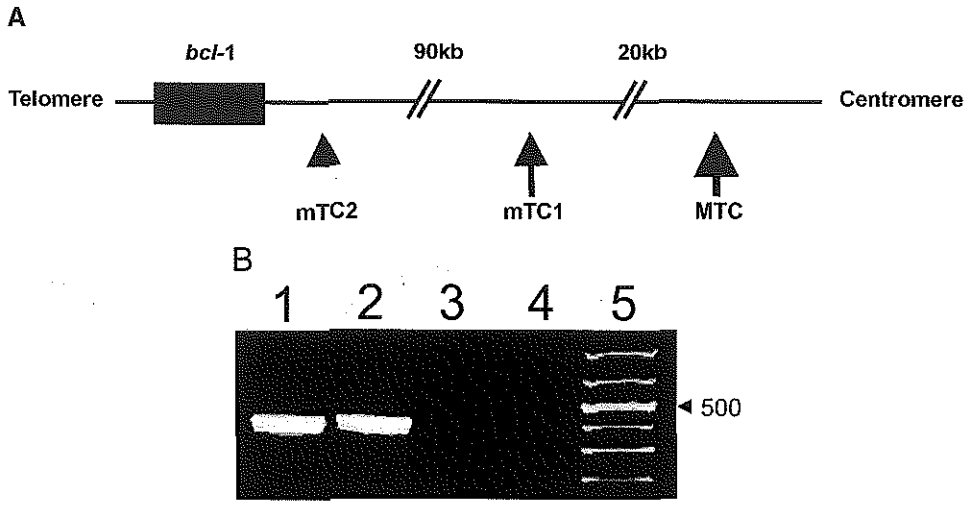

Figure 39-10 A, Schematic representation of the organization of the of the *bcl-1* gene on chromosome 11q13 and the breakpoint regions associated with the t(11;14). The *bcl-1* gene is represented as a white rectangle. The relative locations of the major translocation cluster (MTC) where up to 40% of the breakpoints are clustered and the minor translocation cluster regions (mTC1 and mTC2) are indicated. The size of the amplified PCR product may vary depending on the location of the breakpoints. **B,** PCR analysis and agarose gel electrophoresis for the detection of t(11;14). The primers were directed against the MTC of *bcl-1*. Lane 1 represents a positive control with a band at ~450 bp. Lane 2 is the patient sample with a positive band also at ~450 bp. Lane 3 contains a negative control (reactive tonsil). Lane 4 represents a no-template (H_2O) control. Lane 5 shows the size marker.

the *TEL/AML1* fusion.[45] All of the chimeric proteins that result from the chimeric fusions are dominant negative inhibitors of CBF-mediated transcription.[43,54] The transcriptional repression of the CBF target genes caused by the CBF-chimeric proteins partly involves the recruitment of the histone deacetylase complex.

By comparison, acute promyelocytic leukemia is characterized by translocations involving the *RARA* gene (Table 39-3). These translocations result in a block of myeloid differentiation at the promyelocytic stage. It has been shown that the maturational arrest is due in part to the recruitment of the nuclear co-repressor/histone deacetylase complex. The ability of all-*trans* retinoic acid (ATRA) to bind to *PML*/RARα, resulting in the release of the nuclear co-repressor complex, partly explains the ability of ATRA to relieve the maturational block in promyelocytes that is central to the development of acute promyelocytic leukemia.

t(8;21)(q22;q22)—*AML1-ETO*

The t(8;21)(q22;q22) is found in approximately 7% of de novo AML, and is more common in young individuals. The translocation is found in 20% to 40% of AMLs of the FAB-M2 subtype.[4] It has also been reported infrequently in M1 and M4 subtypes, and in rare cases of therapy associated AML. The translocation leads to the fusion of the *AML1* gene (acute myeloid leukemia 1 gene), also known as *CBFA2* (core binding factor subunit A2), or *PEBP2a* (polyoma enhancer binding protein 2 subunit a) to the *ETO* gene (8;21), also known as *MTG8* (myeloid translocation gene on chromosome 8) and *RUNX1T1*.

The t(8;21) portends a good prognosis in cases of de novo AML, with a favorable response to treatment with cytosine arabinoside.[82] The *AML1-ETO* chimeric fusion is detectable by RT-PCR in the vast majority of t(8;21)-positive AMLs, thus making RT-PCR a good choice for detection of the t(8;21) in clinical samples. The *AML1-ETO* fusions join exon 5 of *AML1* to exon 2 of *ETO* (Figure 39-11), and the fusion transcript can also be detected in complex translocations in a significant proportion of cases that are t(8;21) negative by conventional cytogenetics.[4,78] Specifically, RT-PCR has been reported to detect *AML1-ETO* fusions in 8% to 12% of AML.[4,66,78] Interestingly the *AML1-ETO* fusion transcript may be detected using sensitive end-point PCR assays several years after chemotherapy or a bone marrow transplant (BMT), thus limiting its predictive value for relapse in affected patients.[59] Quantitative studies using recently developed real-time PCR protocols (Figure 39-12 [Color Plate 3]) may provide a better indication of an increase in transcript copies and hence disease recurrence.

t(15;17)(q22;q21)—*PML-RARα*

The t(15;17) is the characteristic molecular abnormality in acute promyelocytic leukemia (APL), which is classified as AML FAB-M3. This abnormality is present in virtually all cases of APL, which constitutes 5% to 10% of all AMLs. The t(15;17) results in juxtaposition of the putative transcription factor *PML* on 15q22[13,74] to the retinoic acid receptor-α gene on 17q21.[89] The breakpoints on chromosome 17 are confined to a 15 kb fragment within intron 2 of the *RARα* locus. The breakpoints on chromosome 15 are more varied, with

t(5;17)(q32;q21)	*NPM/RARA*	AML	FAB M3, coagulopathy, poor retinoic acid response	<1

CML, Chronic myelogenous leukemia; *ALL,* acute lymphoblastic leukemia; *AML,* acute myelogenous leukemia; *p210 and p190,* chimeric proteins (see text); *FAB* (with L3, M3, M4EO, etc), French-American-British classifications; *TRB@, TRD@,* T-cell receptor β and δ loci.
*Estimated frequency per clinical disease category.

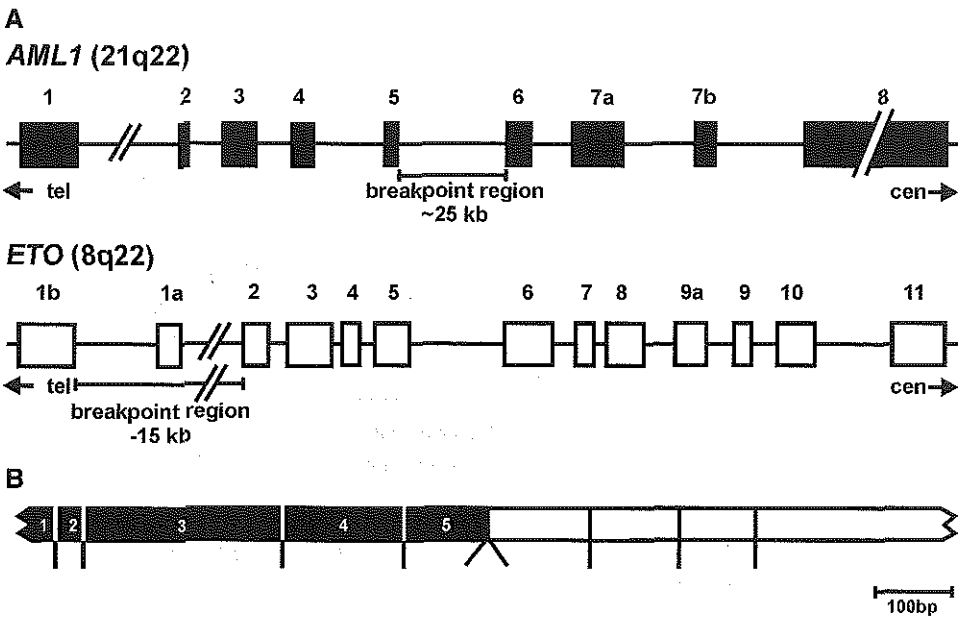

Figure 39-11 Schematic representation of the organization of the *AML1* (21q22) and the *ETO* genes (8q22) involved in the t(8;21) anomaly that is characteristic of FAB AML-M2. The centromeric (c) and telomeric (tel) directions are indicated. In panel A, the exons of the *AML1* gene are depicted in black rectangles; the exons of the *ETO* gene are depicted in white rectangles. In panel B, the configuration of the *AML1/ETO* chimeric fusion is shown. The numbers below the fusion transcript indicate the position of the first nucleotide in the exon involved, or the last nucleotide of the exon immediately 5′ to the fusion.

involvement of three or more breakpoint cluster distinct regions (bcr) (Figure 39-13, *A*). These include intron 6 (*bcr* 1), which is involved in approximately 55% of cases; exon 6 (*bcr* 2), which is involved in 5% of cases; and intron 3 (*bcr* 3), which is involved in 40% of cases. Similar to the scenario seen in the t(9;22) leading to the *BCR-ABL* fusion, the different breakpoints on *PML*, the alternatively spliced transcripts, and usage of two different polyadenylation sites further give rise to a greater variety of *PML-RARα* fusion transcripts of different sizes (Figure 39-13, *B*).[10] Recognition of these varied transcripts is important in the design of diagnostic RT-PCR assays that are capable of detecting the majority of t(15;17) fusions (Figure 39-13, *B*). In this regard, most assays have been directed at the *PML-RARα* fusion, since the reciprocal (*RARα-PML*) fusion is not detectable in some cases of APL. The *PML-RARα* chimeric protein contributes to leukemogenesis by blocking the differentiation of myeloid cells at the level of promyelocytes. Persistent detection of *PML-RARα* transcripts in a treated patient is an ominous indication of a tendency relapse. The recent availability of quantitative real-time protocols provides an opportunity for sensitive and specific monitoring of consecutive samples at appropriate intervals for the identification of patients with high relapse potential.

Chronic Leukemias of Myeloid/Monocytic Lineage

The chronic myeloid leukemias are characterized by translocations that lead to constitutive activation of tyrosine kinases. As mentioned earlier, the most common of these is the t(9;22)(q34;q11), resulting in the *BCR/ABL* fusion that is characteristic of CML. Up to seven different chromosomal translocations are associated with the chronic leukemias of myeloid/monocytic lineage, but all are characterized by the formation of a chimeric fusion with a carboxyterminal tyrosine kinase domain and an oligomerization motif in the amino terminus of the fusion protein. The oligomerization motif is important for the constitutive activation of the tyrosine kinase, which transforms the hematopoietic cells and confers them with ligand-independent growth potential.

t(9;22)(q34;q11)—*BCR-ABL* Aberration

The t(9;22), also known as the Philadelphia chromosome, is the diagnostic hallmark of CML and is found in virtually 100% of cases. The translocation is also found in up to 20% to 50% of acute lymphoblastic leukemias (ALLs) in adults, in 2% to 10% of childhood ALLs, in rare cases of malignant lymphoma, and in myeloma.[11,62-64,75] The t(9;22) results in the juxtaposition of 3′ sequences on the *c-ABL* tyrosine kinase proto-oncogene (9q34), to the 5′ sequences of the breakpoint cluster region *BCR* gene (22q11). The t(9;22) results in the formation of two hybrid genes: *BCR-ABL* on the derivative chromosome 22, and *ABL-BCR* on the derivative chromosome 9.[25] The *BCR-ABL* fusion encodes a chimeric protein with constitutively activated tyrosine kinase activity. While the breakpoints on chromosome 9 are relatively constant and 5′ to exon 2 of c-*ABL*, the breakpoints on chromosome 22 are quite variable and within the *BCR* gene (Figure 39-14).[53,62] Depending on the location of the breakpoint, the fusion protein resulting from the *BCR-ABL* fusion could vary in size from 190 to 230 kDa. Up to 95% of CMLs, 30% to 50% of adult t(9;22) positive ALLs, and 20% to 30% of childhood t(9;22)-positive ALLs harbor breakpoints in the m-*BCR* region of the *BCR* gene.[48,87,91,101] The *BCR* breakpoints in virtually all of the CML cases occur in the 9.0 kb region between exons 13 and 15 (also known as b2 and b4, respectively). Fusion is

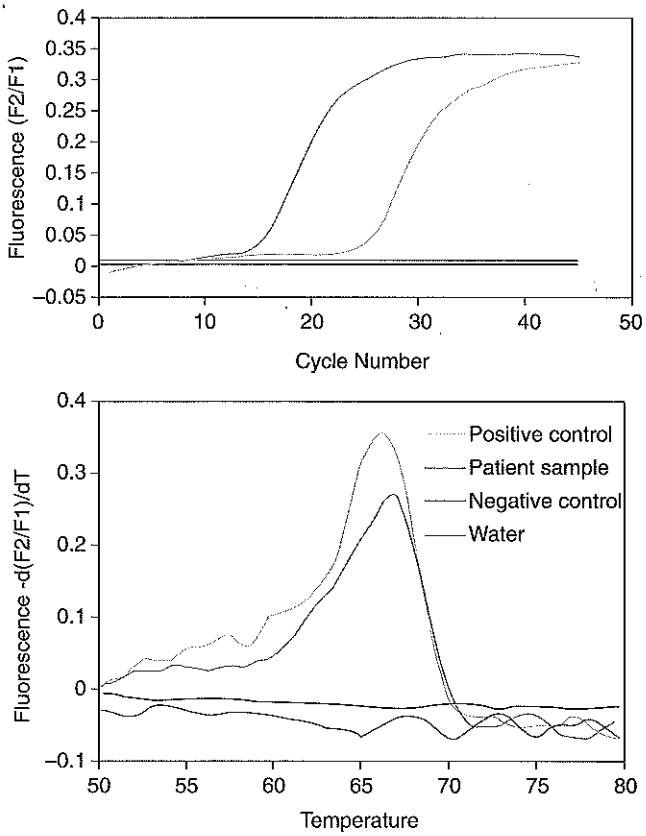

Figure 39-12 Real-time PCR detection of *AML1/ETO* fusion transcript. Real-time PCR detection was performed using a sequence-specific hybridization probe format with oligonucleotide probes labeled with fluorescein as the donor fluorophore and LCRed640 as the acceptor. Postamplification melting analysis was performed to provide confirmation of amplicon identity through the probe melting temperature. Panel A shows the fluorescence (F) versus cycle number (C) on the LightCycler™ (Roche Diagnostics). The characteristic three-phase profiles of amplification curves are recognizable (i.e., initial lag, exponential or log/linear, and the final plateau phase). The red curve represents the positive amplification signal for the t(8;21) in the Kasumi cell line positive control. The blue curve represents the patient sample also showing the presence of the *AML1/ETO* fusion. The green line represents a negative control (placental cDNA), and the black line is the no-template (H_2O) control. Panel B shows the derivative melting curves with positive melting peaks at ~65°C in both the Kasumi cell line positive control and the patient sample. Both the negative and water controls show flat lines indicating the absence of the t(8;21) *AML1/ETO* product. (See Color Plate 3.)

to a breakpoint located in the large intron between exons 1b and 2 of the *ABL* gene[20] (Figure 39-14). The resulting *BCR-ABL* transcript measures 8.5 kb and contains either *BCR* exon b2 or b3 and *ABL* exon 2 (exon a2). This transcript encodes the 210 kDa *BCR-ABL* chimeric protein ($p210^{BCR/ABL}$). The most common fusions found in CML are b3-a2 fusions, accounting for 55% of the *BCR-ABL* junctions, and b2-a2 (40%).[107] Less frequently (5%), both the b3-a2 and b2-a2 fusions may occur as a result of alternative splicing.[107] Thus far, there appear to be no significant prognostic differences between p210-positive CMLs with different transcripts.[107]

In rare cases of CML, the breakpoint in the *BCR* gene occurs at the ALL-associated m-*BCR*, which leads to the generation of the $p190^{BCR/ABL}$ fusion protein.[105] p190-positive CML patients characteristically exhibit relative and absolute monocytosis in peripheral blood reminiscent of chronic myelomonocytic leukemia.[77] Another distinct but rare fusion that has been described in t(9;22)-positive CML is one that results in the formation of a large 230 kDa fusion protein as a consequence of a fusion between exon 19 (c3) of *BCR* and exon 2 (a2) of *ABL*. The *BCR* breakpoints for this fusion are located in the micro breakpoint cluster region (μ-*BCR*) located between exons 19 and 20 (see Figure 39-14). The p230 fusion is characteristic of a peculiar form of CML with prominent neutrophilic proliferation. The clinical course of p230-positive CML is reportedly indolent in the majority of cases.[88]

Another distinct breakpoint cluster region in the *BCR* gene has been uniquely associated with t(9;22)-positive ALLs.[53] Up to 60% of t(9;22)-positive ALL carry translocations in which the breakpoints are located in a distinct region known as the "minor breakpoint cluster region" (m-*BCR*). m-*BCR* is located between the two alternative exons and exon 2 (see Figure 39-14). The *ABL* breakpoints are located in the large intron between exon 1b and exon 2 of the *ABL* gene (see Figure 39-14). The resulting e1-a2 fusion encodes a 190 kD *BCR-ABL* chimeric protein[21] that is expressed mostly in *ALLs*, and rather infrequently as the exclusive *BCR-ABL* transcript in CML.[96,105] On the other hand, the remaining 40% of t(9;22)-positive ALLs may express the p210 *BCR-ABL* fusion, thus indicating its relative lack of specificity. A significant number of CML cases also express low levels of e1-a2 transcripts in addition to p210 via an alternative splicing mechanism.[23,56,96,119]

Conventional cytogenetics, FISH, and RT-PCR have been reliably used for the laboratory detection of the t(9;22). RT-PCR detection is possible in up to 95% of cases, and may detect up to 10% of cases missed by conventional cytogenetics,[23] and is an important modality for minimal residual disease detection. Recently, quantitative real-time PCR-based approaches have improved the ability to detect and quantify *BCR-ABL* transcripts in CML patients[32,61] (Figure 39-15 [Color Plate 4]). The recent availability the tyrosine kinase inhibitor imatinib mesylate for CML is an important development in the treatment of CML[31,32] and further underscores the importance of methods for sensitive and specific identification and quantification of the *BCR-ABL* fusions in patients with a clinical suspicion of a CML.

t(9;22) in Acute Lymphoblastic Leukemia

The t(9;22) has emerged as a sine qua non for the diagnosis of CML, and the recent development of novel tyrosine kinase inhibitor therapy portends a favorable prognosis. By con-

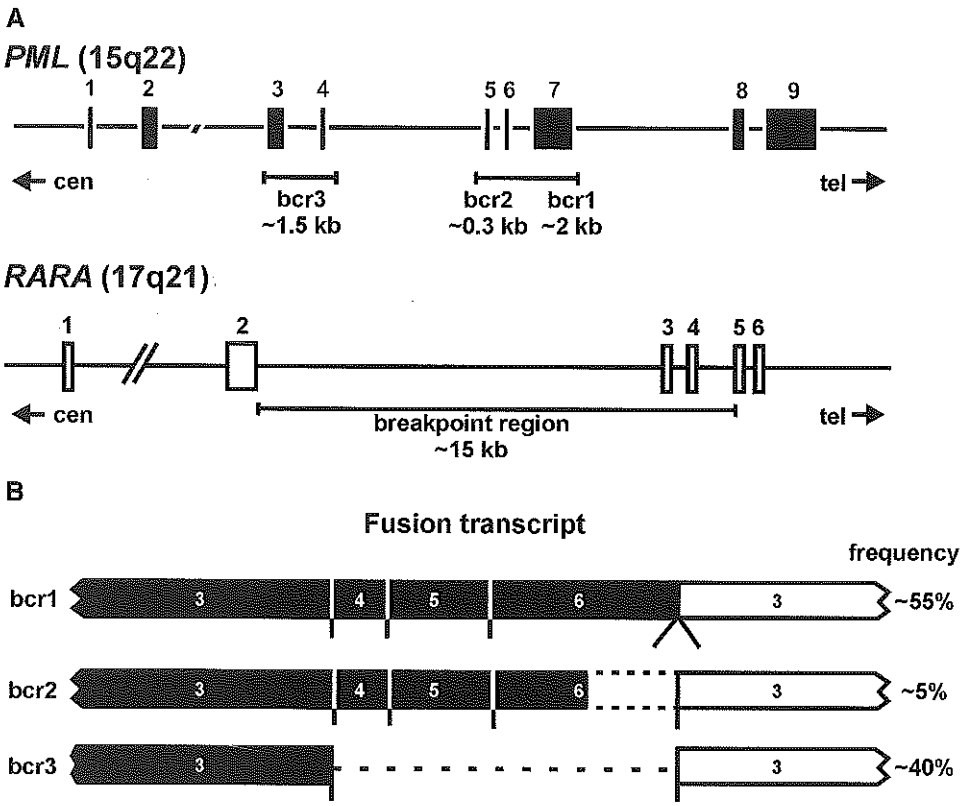

Figure 39-13 Schematic representation of the organization of the *PML* (15q22) and *RARα* (17q11) genes involved in the t(15;17) anomaly, which is characteristic of FAB AML-M3. The centromeric (c) and telomeric (tel) directions are indicated. In panel A, the exons of the *PML* gene are depicted in black rectangles, and the exons of the *RARα* gene are depicted in white rectangles. In panel B, the configuration of the *PML-RARα* chimeric fusions are shown.

trast, the presence of the t(9;22) is an independent poor prognostic factor in ALLs.[41,102,125]

Use of Reverse-Transcription Polymerase Chain Reaction in Chromosomal Translocations

Reverse-transcription polymerase chain reaction (RT-PCR) is particularly indicated in the detection of chromosomal translocations wherein the breakpoints are widely dispersed with large intervening introns between the juxtaposed fragments that limit the practicality of conventional PCR. As RT-PCR begins with synthesis of complementary (cDNA) from mRNA (with use of oligo-dT priming, random hexamers, or gene-specific primers), the template for the PCR is not the genomic DNA, but the complementary DNA derived from the reverse-transcribed RNA. RT-PCR for identification of a characteristic chromosomal translocation will be addressed later using the example of the t(9;22), which is present in virtually 100% of cases of chronic myeloid leukemias and in a smaller subset of acute lymphoblastic leukemias.

Real-Time Polymerase Chain Reaction Methods

The PCR assays traditionally used in the study of hematological malignancies have entailed a two-step procedure comprising an initial amplification reaction, followed by analysis of the PCR products in a separate process. PCR product analysis has generally entailed size fractionation by gel electrophoresis and product visualization by ultraviolet (UV) illumination of ethidium bromide–stained gels or by chemiluminescent or radioisotopic detection. The recent advent of real-time PCR techniques now permits PCR amplification with simultaneous monitoring of product accumulation.[55] Real-time PCR methodologies employ variations of fundamental fluorescence chemistries to monitor product accumulation. Higuchi et al introduced the incorporation of a double-stranded DNA (dsDNA) binding dye (ethidium bromide) into amplification reactions, with fluorescence monitoring at each cycle for quantitative analysis.[55] Such real-time PCR assays using dsDNA-binding dyes, such as ethidium bromide and SYBR Green I, are relatively inexpensive and easy to use, but suffer the drawback that they do not offer specificity beyond that inherent in the PCR. In poorly optimized reactions, the nonspecific dsDNA binding dye- or intercalator-based assays can yield false-positive results. It is thus important to carefully optimize primer design to discourage primer-dimer and nonspecific product formation.[16]

For studies of hematological malignancies, the sequence-specific fluorescence probe–based systems provide the advantage of an important further test for identification of the sequence of interest by virtue of hybridization of fluorescently labeled internal probes to the amplified target sequence.[127] The most commonly used sequence-specific chemistries include the exonuclease (TaqMan), the linear hybridization probe, and the hairpin-based (Molecular Beacon) systems. (See Chapter 37 for further information on nucleic acid techniques.)

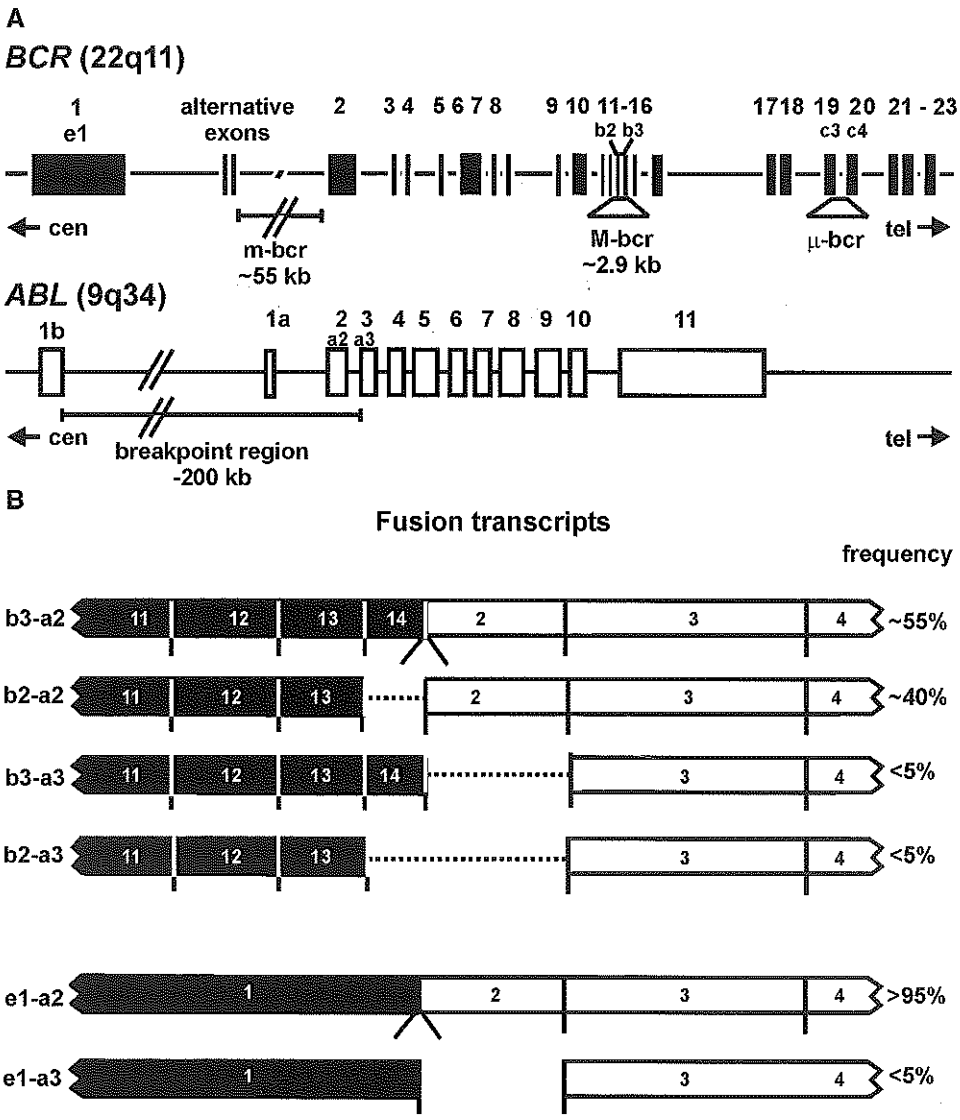

Figure 39-14 Schematic representation of the *BCR* (22q11) and *ABL* (9q34) genes involved in the t(9;22), which is characteristic of all CMLs and a subset of *ALLs*. The centromeric (cen) and telomeric (tel) directions are indicated. The relative positions of the major breakpoint cluster (M-*BCR*), the minor breakpoint cluster (m-*BCR*), and the micro breakpoint cluster regions (μ-*BCR*) are shown. The previously used alternative nomenclature for the *BCR* and *ABL* exons is included where relevant. In panel A, the exons of the *BCR* genes are depicted in black rectangles, and those of the *ABL* genes are depicted in white rectangles. In panel B, the configuration and varieties of the *BCR-ABL* chimeric fusions seen in CML are shown. In the lower part of panel B, the configuration and varieties of the *BCR-ABL* fusions seen in *ALL* are shown. The e1-a2 transcript is most commonly detected in t(9;22)-positive *ALL*, while the b3-a2 and b2-a2 fusions are the most commonly detected in CML.

Quantification

Real-time PCR is particularly advantageous for the quantitative analysis of nucleic acid sequences. Previously, quantitative PCR was based on end-point or competitive assays that measured band intensities in ethidium bromide–stained gels, or hybridization-based approaches using radioisotopic labeling and densitometry.[120] Fluorescence-based, real-time PCR assays characteristically demonstrate three phases: an initial background phase, an exponential or logarithmic phase, and a plateau phase. The exponential phase starts after the background phase and occurs when product accumulation rises significantly above background levels, and ends at the beginning of the plateau phase. The plateau phase occurs as a result of a combination of factors, including the accumulation of reaction products, ineffective polymerase activity, and competition of the accumulated PCR product for the oligonucleotide primers. The onset of the log-linear phase is inversely related to the abundance of the target of interest at the beginning of the PCR. By using calibrators with known quantities of a specific target, a calibration curve can be plotted with a crossing threshold (y-axis) against log concentration (x-axis) for the target of interest. The crossing threshold for a control and specific gene targets in unknown samples can be derived from their PCRs and read off the calibration curve to yield a copy number for the target transcript. By contrast, traditional methods require multiple amplification reactions in several tubes, which is labor-intensive and could lead to inaccurate results.

ONCOGENE AND TUMOR SUPPRESSOR GENE MUTATIONS IN HEMATOPOIETIC MALIGNANCIES

The concomitant occurrence of additional genetic aberrations and chromosomal translocations is common in hematological malignancies. The *RAS* oncogene is one of the most frequently mutated genes in cancer,[14] and is mutated in up

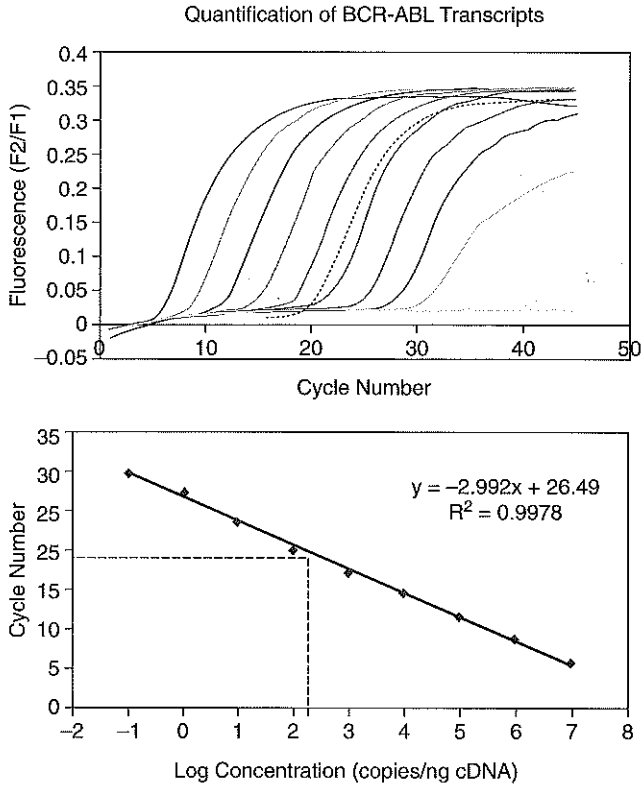

Figure 39-15 Real-time quantitative PCR of *BCR-ABL* transcripts. Serial log dilutions of the plasmids containing the *BCR-ABL* transcripts. Real-time PCR provides a remarkable dynamic range of quantification (10^9 to 10^0 template copies) in this example. The upper panel shows the amplification curves obtained using the *BCR-ABL* containing plasmids and an unknown patient sample depicted as a dotted line. Note the regular ~3.3-cycle interval between log dilutions. The lower panel shows a standard curve (linear regression of cycle number versus log template concentration). As indicated by the dotted line in the lower panel, the cycle threshold (onset of the log-linear phase of the amplification curve) can be used to quantitate the copy number of the target in the tested sample. (See Color Plate 4.)

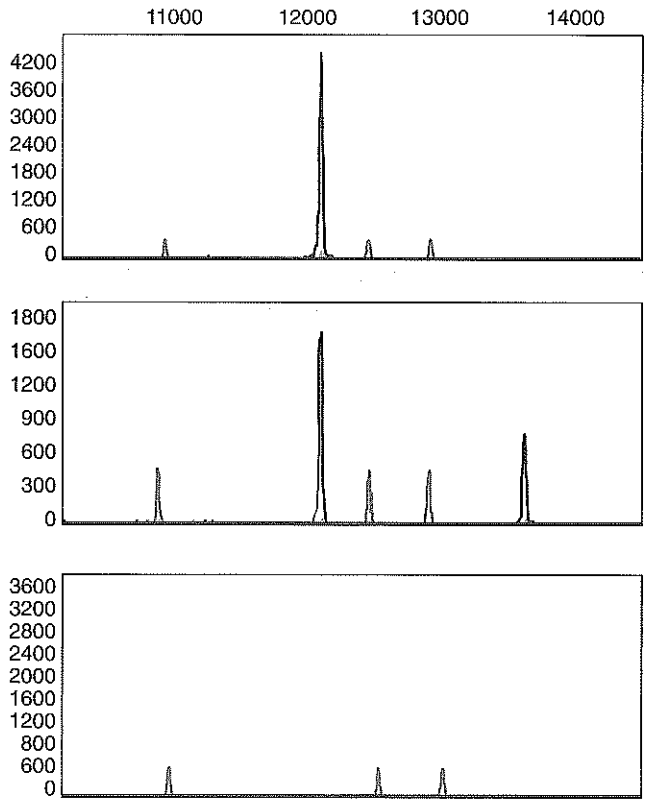

Figure 39-16 Detection of internal tandem duplications of the *FLT3* gene by PCR and capillary gel electrophoresis of PCR products. Capillary electropherograms show clear resolution of PCR products. The x-axis represents the sizes of PCR products and the y-axis shows the fluorescence intensity, which correlates with the abundance of the PCR product. The upper panel shows a wild type of pattern (blue peak). The middle panel shows an additional peak of greater size than the wild-type peak (blue peak on the left). The blue peak on the right represents a *FLT3* internal tandem duplication. The lower panel shows the size markers (red peaks) also present in the upper and middle panels. (See Color Plate 5.)

to 25% to 44% of hematopoietic malignancies and myelodysplastic syndromes (MDS).[7] The presence of *RAS* mutations has been reported to portend a worse prognosis in patients with AML and MDS.[84,85] The mutations are clustered in "hot spots" occurring at codons 12, 13, or 61, rendering them fairly easy to detect using different strategies for mutation detection, such as single strand conformation polymorphism analysis (SSCP) and denaturing gradient gel electrophoresis (DGGE).

Mutations of another tyrosine kinase, *FLT3*, have been described in acute myeloid leukemias.[83,128] The majority of these mutations are internal tandem duplications (ITDs) within the juxtamembrane domain (JMD) of the gene, and are present in up to 24% of AML cases. ITDs have been identified in all FAB subtypes of AML, most frequently in acute promyelocytic leukemia (AML FAB-M3). Figure 39-16 (Color Plate 5) shows an example of an *FLT3* ITD detected by PCR and capillary electrophoresis in a case of acute myeloid leukemia, which also demonstrated the presence of the *PML-RARA* fusion transcript. The presence of the ITD was inferred by the larger PCR product size (Figure 39-16 [Color Plate 5]) and was subsequently confirmed by sequencing. Additional mutations distinct from the ITDs occurring in the JMD have been described in a subset of AMLs. The most common of these is a base substitution occurring at the codon for aspartic acid residue 835 in the activation loop of *FLT3*. D835 mutations have been identified in 7% of AML, 3% of MDS, and 3% of ALLs.[128] If *FLT3* ITDs and activation mutations are combined, *FLT3* may be the most frequently mutated gene in acute myeloid leukemia. Mutations in the activation loop of another receptor tyrosine kinase *C-KIT* have been reported in mast cell proliferations,[73] and in a small proportion of AMLs.[17]

The *P53* gene is a tumor suppressor gene that encodes a nuclear phosphoprotein/transcription factor, which regu-

lates diverse cellular processes, including DNA repair, cell-cycle arrest, and apoptosis. p53 inactivation is associated with genomic instability, and deregulated cell cycle entry and progression. The p53 gene is the most commonly mutated tumor suppressor gene in cancer. p53 mutations are commonly present in a variety of hematological disorders, including blast crisis in CML, AML, MDS,[68,122] and adult T-cell leukemia/lymphoma.[97] p53 mutations are also implicated in the histological transformation of follicular lymphoma into diffuse large B-cell lymphoma[98] and have been described in a small subset of cases of Hodgkin lymphoma.[37] p53 mutations correlate with resistance to chemotherapy and portend a worse prognosis.[122] The p53 mutations are localized mainly to mutational "hot spots" in exons 5 to 8 and may be single base substitutions, deletions, or insertions. Dominant negative inactivation of critical p53 protein function can be achieved by a mutation on one allele, since the wild type protein can dimerize with mutated proteins, resulting in functional impairment of p53 protein activity.[44] DGGE,[49] constant denaturant gel electrophoresis,[12] and SSCP[37] have been used with great success for the detection of p53 mutations and can serve as effective screening tools in the molecular laboratory.

MINIMAL RESIDUAL DISEASE DETECTION AND MONITORING

The occurrence of characteristic genetic aberrations and the uniqueness of antigen-receptor gene rearrangements in lymphoid neoplasia provide an attractive opportunity for the exploitation of the high sensitivity and specificity of molecular techniques for the detection of minimal residual disease and therapeutic monitoring. The sensitivity and specificity of molecular techniques in being capable of detecting one aberrant cell in a background of 10^{3-6} are superior to those provided solely by clinical or microscopic examination.

PCR-based studies have enjoyed their greatest utility for the detection of clonal antigen-receptor rearrangements and recurrent chromosomal translocations. In antigen-receptor gene rearrangements, clonal identity may be established either by designing sequence-specific primers for the unique antigen-receptor rearrangement, or by sequencing the PCR product from the subsequent sample.

The ideal scenario for the analysis of antigen-receptor rearrangements for monitoring of minimal residual disease (MRD) requires identification of the sequence of the specific clonal antigen-receptor gene rearrangement in the tumor of interest, followed by clonality analysis and sequencing of the initial and subsequent samples. The antigen-receptor gene rearrangement sequences of the initial and subsequent biopsies are compared for sequence homology. Alternatively, tumor-specific antigen-receptor primers may be designed for amplification of the subsequent sample, with successful amplification being considered evidence of clonal identity.

MRD testing using antigen-receptor PCR-based monitoring is especially significant in the pediatric population in patients with acute lymphoblastic leukemia/lymphoma.[79] The detection of clonal rearrangements of the antigen-receptor genes at the end of induction therapy has been shown to be predictive of a high relapse potential.[40,121] In addition, the demonstration of persistent positivity in successive analyses is a good indicator of future clinical relapse, while persistent negativity is indicative of a durable remission.[110]

The detection of chromosomal aberrations by PCR-based methods continues to evolve as a tool for MRD detection. Indeed the clinical significance of the qualitative detection of chromosomal translocations has been the subject of intense study with varying implications depending on the natural biology of the hematological disorder (if present), the specific clinical context, the translocation detected, or the methodology employed. For instance, t(14;18) has been detected in the peripheral blood and reactive lymphoid tissues of healthy individuals, leading to uncertainty about the significance of the qualitative detection of the t(14;18).[30,71] Similarly, highly sensitive PCR assays have detected the t(9;22) in the peripheral blood of otherwise healthy elderly individuals.[9,15]

The implications of qualitative detection of translocations vary with the translocation detected. For instance, there is a very high risk of relapse associated with the detection of residual *PML-RARα* transcripts after therapy.[28,29] By contrast, the t(8;21) *AML1-ETO* fusion may be detected in patients who have sustained and durable clinical remissions following treatment. The *AML1-ETO* fusion may be also detected in patients who have undergone chemotherapy or bone marrow transplantation.[59,65] On the other hand, the detection of the t(9;22) *BCR-ABL* fusion transcript is most prognostically significant for relapse if conversion to positivity occurs within 6 to 12 months of treatment. The predictive value of the presence of the chimeric transcripts can be affected by therapy-associated factors, such as graft-versus-host disease and type of transplant.[92] Nevertheless, persistent molecular negativity for the *BCR-ABL* transcript is indicative of good response to therapy and favors a durable remission.

The recent availability of quantitative real-time PCR-based assays for the quantitative detection of specific genetic alterations holds great promise in the quantification of tumor burden, response to therapy, and relapse potential. Appropriately done, the tests should be performed at a series of regular and successive time-points during the management of the disease. This approach is more apt to identify increasing, decreasing, or stabilizing trends in the abundance of the translocation product in tested samples. Figure 39-15 (Color Plate 4) show a quantitative RT-PCR study for the *BCR-ABL* transcript that incorporates several calibrators for the determination of the number of copies of the fusion transcript present in the sample. An alternative approach involves the determination of the ratio of the expression levels of the fusion transcript being tested against that of a stably expressed house-keeping gene, and monitoring the changes that ensue over time.

DETECTION OF VIRAL GENOMES

Viruses involved in the pathogenesis of abnormal proliferations of hematopoietic cells include the human T-cell leukemia virus type I found in adult T-cell leukemia/lymphoma and Kaposi-sarcoma herpesvirus/human herpesvirus-8 (KSHV/HHV8) seen in Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman's disease.[18] All of these viruses can be detected using the standard molecular biology techniques described in this chapter. PCR is commonly used because of its speed and ease of performance. Primer design should take into consideration the propensity for shared sequences within related viruses. Optimal specificity can be obtained by designing primers to unique portions of the genome of the virus of interest. Because of its well-established role in the pathogenesis of a variety of lymphoproliferative disorders, Epstein-Barr virus (EBV) and its detection are discussed below as an example of a virus that may be detected by in situ hybridization.

EPSTEIN-BARR VIRUS

EBV was identified in 1964 by Epstein, Achong, and Barr in cultured cells obtained from a malignant lymphoma described by Dennis Burkitt.[38] EBV was subsequently identified by Werner Henle and colleagues as the cause of infectious mononucleosis.[52] EBV is a lymphotropic virus that has been associated with several malignant neoplasms including endemic Burkitt lymphoma, nasopharyngeal carcinoma, nasal T/NK-type lymphoma, and some subtypes of Hodgkin lymphoma. EBV is also implicated in the pathogenesis of the majority of posttransplant lymphoproliferative disorders.[58]

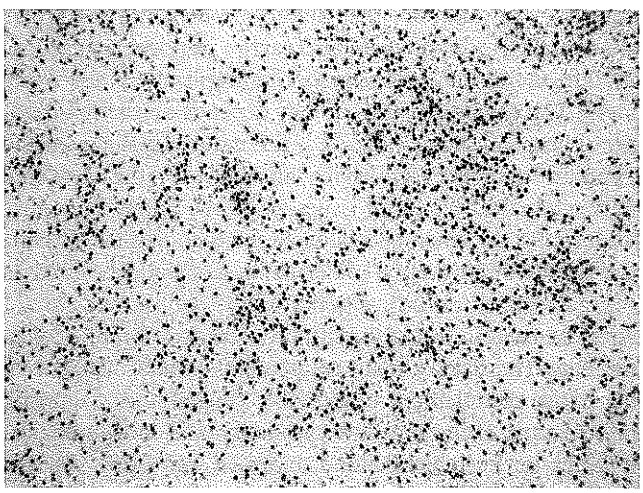

Figure 39-17 In situ hybridization (ISH) for the Epstein-Barr virus (EBV). ISH hybridization for EBV shows numerous positive signals (dark-blue spots) for EBV using the EBER-1 probe. The tissue sample was obtained from a solid-organ transplant patient who developed widespread nodal and extranodal masses. The positive reaction for EBV in this assay supports a diagnosis of posttransplant lymphoproliferative disease. (See Color Plate 6.)

Figure 39-17 (Color Plate 6) shows an example of positive EBV in situ hybridization in a case of posttransplant lymphoproliferative disease.

EBV is an enveloped icosahedral virus containing a double-stranded DNA genome of 172 kb with more than 100 open reading frames, potentially encoding an equivalent number of proteins.[6] The precise size of each virion varies from particle to particle because of the presence of tandemly repeated sequences, each 500 bp long, present in the virus termini. Viral tropism is mediated via attachment of the gp350/220 viral envelope protein to the complement receptor type 2 C3d (CR2) or CD21.[42,112] The virus exhibits tropism for B-cells, some T-cells, dendritic cells, and epithelial cells. After infection, typically via the oropharyngeal mucosa, EBV undergoes lytic replication in vivo. In the lytic replication, the linear genome is duplicated, assembled into viral capsid, and eliminated from the cell by budding or lysis. By contrast, B-cells are efficiently immortalized by EBV in vitro. In immortalized cells, the viral genome is circularized by fusion of the termini (episomal), and the viral infection is latent with lack of production of viral particles. In the latent phase, viral replication occurs coordinately with host cell division. During latent infection, 11 genes are actively transcribed, including 6 nuclear antigens (EBNA-1, -2, -3A, -3B, -3C, -LP), 3 membrane proteins (latent membrane proteins LMP-1, -2A and -2B), and 2 EBV-encoded small nonpolyadenylated RNAs (EBER-1/-2).[3] The EBERs are present at very high copy numbers in the nuclei of latently infected cells.[69] The abundance of this transcript makes it attractive for detection of latent EBV infection in cells and tissue specimens by in situ hybridization (see Figure 39-17 [Color Plate 6]). Three latency patterns of expression have been described that relate to the expression of latency gene products. In latency pattern I, exemplified by Burkitt lymphoma cells, EBNA-1 is the only antigen that is expressed. In latency pattern II (exemplified by Hodgkin lymphoma), EBNA-1 and LMP-1 are expressed, and in latency pattern III (exemplified by posttransplant lymphoproliferative disease), all nuclear and latent membrane antigens are expressed. Based on the premise that one virion infects one host cell, and each virion has a unique number of terminal repeats with each episome being exactly replicated in all of its progeny, the clonality status of different cell populations has been assessed using probes complementary to the EBV termini by SBH analysis.[50] Genomic probes that are complementary to sequences adjacent to the EBV termini (called terminal repeat region probes) are used. In this assay, a specimen yielding a single size of episomal EBV DNA is considered monoclonal. This is based on the premise that all of the cells arose from a parent cell containing the same EBV DNA episome that was replicated in the progeny. By contrast, a sample yielding various sized episomes, with a ladder pattern in which fragments differ by 500 bp, is indicative of a polyclonal population wherein each progenitor cell harbored a different EBV DNA episome.[90] An obvious advantage of using EBV terminal repeat probes for assessment of clonality is that it

can also be used for assessment of clonality in EBV-positive nonhematopoietic neoplasms (e.g., nasopharyngeal carcinoma) in which antigen-receptor gene rearrangements are not informative.[90] EBV in situ hybridization using probes targeting the EBER-1 transcript has contributed significantly to the identification of EBV in several hematopoietic and nonhematopoietic disorders.

IN SITU HYBRIDIZATION

The ability to visualize the cellular localization of different gene products is an important aspect of molecular biology and pathology. In situ hybridization (ISH) permits identification of the exact cellular location of target DNA or RNA in cytological preparations or microscopic sections. ISH uses a nucleic acid (DNA or RNA) probe that is complementary to the gene sequence of interest. The probe may be labeled by nonisotopic or radioisotopic methods. ISH hybridization of fixed paraffin-embedded tissue sections entails initial dissolution of paraffin in xylene and serial rehydration in aqueous solutions of ethanol with decreasing ethanol contents ("graded ethanols"). For DNA targets, the tissue section is subjected to denaturation, followed by application of the probe for hybridization. Several washing steps with modulation of stringency (temperature, ionic/salt concentration) are necessary to ensure specificity of the hybridization. Development of signals indicative of specific hybridization depends on the system used. Colorimetric detection using the avidin-biotin system and peroxidase chemistry with a substrate (e.g., diaminobenzidine) yielding a visible precipitate is currently favored for light microscopic applications.

ISH is versatile and can be used for the detection of viral targets and for a number of other diagnostic tests including in the assessment of B-cell clonality by light chain restriction. Recent developments that have led to widespread utility of ISH include the development of nonfluorescent chromophore in situ hybridization protocols that permit the ISH analysis of a variety of targets using the light microscope.[8]

POTENTIAL OF MICROARRAYS IN MOLECULAR DIAGNOSTICS OF HEMATOLOGICAL MALIGNANCIES

The recent advent of high-density oligonucleotides or cDNA array formats that permit the simultaneous evaluation of the expression status of thousands of genes in a single hybridization experiment promises to revolutionize the molecular diagnosis of hematological malignancies. Microarrays are prepared by immobilization of nucleic acid sequences onto glass slides.[99,100] In the cDNA hybridization format, the expression level of a transcript in one sample is compared with that in another sample in a competitive hybridization. The mRNA from the samples of interest is extracted and reverse transcribed to produce cDNA. cDNA from each sample is labeled with a different fluorophore—such as Cy5, which emits in the red spectrum, and Cy3, which emits in the green spectrum. The labeled samples are mixed and hybridized to the array. The hybridization signals are captured by a laser confocal microscope scanner. The ratio of Cy5/Cy3 fluorescence for each gene (i.e., red versus green) is computed and yields data that reflect the relative levels of expression of the interrogated gene in the test and the reference samples.

The technique provides an impressive dynamic range for quantification of several genes in a single experiment, and permits the determination of profiles that reflect the molecular signature of a specific tumor category. Integration of the vast amounts of information obtained from microarray experiments requires the use of sophisticated bioinformatics tools and algorithms to obtain biologically meaningful information.[33,46,93] Microarrays have been used in class distinction,[46] class discovery,[2] and class prognostication of outcomes in processes with distinct expression profiles.[2,108] More recently, microarray analysis has been employed in the elucidation of molecular and cellular signaling pathways that are involved in the pathogenesis of hematopoietic malignancies.[36] The potential of this technology to reveal novel markers for accurate disease diagnosis and prognosis, and markers of chemoresistance or predictors of rapid response to therapy makes it attractive for molecular diagnostics of these conditions. It is envisaged that smaller, highly predictive gene sets will be assembled in disease-related diagnostic "chips" for the assessment of specific categories of hematological malignancies and other diseases.

CONCLUSIONS

Hematopoietic neoplasms are associated with distinctive molecular aberrations that are amenable to diagnostic detection. In addition, the identification of the molecular abnormality in many cases also carries important prognostic information and disease-specific implications for treatment. The choice of methodology depends on the nature of the aberration being evaluated, the nature of the available samples, and the sensitivity afforded by the available methodologies. Technical issues aside, the potential contribution of a test must be evaluated for each patient individually. Most importantly, molecular tests should be used as adjunctive tools in the evaluation of the patient, and should never be used in isolation without consideration of clinical findings. The management of a patient should incorporate the entire complement of available clinical and diagnostic information, including flow cytometry and morphological findings on peripheral blood, biopsies, and bone marrow aspirates. Ideally, all this information could be analyzed and synthesized to produce a final diagnostic report that incorporates these findings.

CHAPTER 40

Inherited Diseases

Cindy L. Vnencak-Jones, Ph.D.

Since the first description of the use of the polymerase chain reaction (PCR) for the diagnosis of sickle cell anemia in 1985, numerous applications of PCR have been described.[38,503] The invention of PCR coupled with advances in computer technology and the chemistry of fluorescent molecules have revolutionized the field of human genetics and enabled the accelerated completion of the Human Genome Project. In more recent years, the Internet has enhanced the growth of this discipline and aided in a phenomenal number of discoveries by enabling rapid exchange of information and unrestricted communication among investigators around the world.

This chapter will review deoxyribonucleic acid (DNA) testing for some of the more common inherited autosomal recessive, autosomal dominant, and X-linked genetic diseases, and discuss testing of several mitochondrial, imprinting, and complex diseases. Since molecular testing for inherited diseases has impacted virtually every discipline of clinical medicine, the reader should refer to other chapters within this textbook for discipline-specific diseases, including inherited disorders of erythrocyte enzymes (see Chapter 21) and inborn errors of carbohydrate metabolism (see Chapter 25). In this rapidly evolving area of diagnostic testing, although testing for the same disease occurs in many clinical laboratories, multiple methodologies can be used to achieve the same sensitivity and specificity. Similar to other areas of laboratory medicine, the methodology chosen by the DNA laboratory is determined by the expected volume for the test, the availability of personnel to perform the assay, the current instrumentation within the laboratory, and the accessibility of funds for capital equipment.

In conjunction with the scientific discoveries that have been made in the area of human genetics, equally explosive has been the public awareness of DNA and genetic diseases through the media and the Internet. During the next 20 years, we as scientists and as a society will debate various issues. Which genetic tests will be used for routine carrier or diagnostic screening? Who has a right to know the results of genetic testing? The insurance company? The employer? Will knowledge of this information cause discrimination or stigmatization? Once we begin to unravel the interaction between genetic and environmental factors, can insurance or healthcare coverage be denied to the person who engages in a lifestyle likely to cause disease based on their genetic predisposition? How will the healthcare system absorb the cost of these expensive assays? Can the healthcare community be trained to understand complex principles of genetics and provide comprehensive counseling? Can a person's genetic makeup predisposing them to aberrant behavior provide a defense in a court of law? To what extent will manipulation of genetic material be tolerated in our society? Will most couples undergo in vitro fertilization and preimplantation genetic screening to choose the embryo with the most desirable genes? Will cloning be allowed? Will embryonic stem cell research be routine? Although it is difficult to predict what the future will bring, one thing is clear: the future will be both scientifically and intellectually stimulating, yet no doubt controversial.

DISEASES WITH MENDELIAN INHERITANCE

Autosomal Recessive Diseases

An individual with an autosomal recessive disease has inherited two abnormal alleles at a given locus by receiving one mutant allele from each carrier parent, and the disease-causing gene is on one of the autosomes (1 to 22) and not a sex chromosomes (X or Y). Typically the carrier parent with one abnormal allele has no clinical features of the disease yet possesses a 50% risk of donating the mutant allele to his or her offspring. Matings in which both partners are carriers of an abnormal allele have a 25% chance of having a child with both normal alleles, a 50% chance of having a child that has received only one abnormal allele, and a 25% chance of having an affected child. The affected patient may be homozygous for a specific mutation by receiving the same mutation from each parent or may be a compound

heterozygote having received a different mutation within the gene from each parent. Regardless of the mechanism, the end result is the same; the patient has no normal allele. However, the specific mutations present in the patient can affect the clinical severity of the disease. In pedigrees illustrating autosomal recessive disorders, both males and females are equally affected, and for rare diseases, consanguinity is likely to be observed.

Cystic Fibrosis

Cystic fibrosis (CF) is one of the most common autosomal recessive diseases in people of Northern European ancestry with an estimated incidence in the United States of about 1 in 3200 and a carrier frequency of about 1 in 29.[236] The frequency of the disease within other ethnic populations is much lower with an estimated incidence of 1 in 9200 in U.S. Hispanics, 1 in 10,900 in Native Americans, 1 in 15,000 in African Americans, and 1 in 31,000 in Asian Americans.[236] CF is a multisystem disorder affecting the pulmonary, gastrointestinal, and reproductive organs. However, the phenotypic expression of the disease is heterogeneous, ranging from meconium ileus and severe respiratory disease in infants to mild pulmonary symptoms and no evidence of gastrointestinal problems even in adulthood. Morbidity and mortality of the disease are most related to mucus accumulation; recurrent infections with unusual pathogens, such as *Pseudomonas aeruginosa;* and excessive inflammation in the lung. Although in the past, CF resulted in death in early childhood for most patients, the U.S. Cystic Fibrosis Foundation reported in September 2000 that the median survival age among 22,301 patients ranging from 1 month to 74 years was 32.2 years, with about 40% of patients living past the age of 18.[125] This represents a significant increase from just 1 decade earlier (1990) when data from 17,857 patients showed the median age at 12.5 years, with about 33% of patients representing adults.[180] The increased survival age is largely caused by organ transplantation, improved nutrition, and new drug therapies and is likely to continue to increase with the potential of successful gene therapy to the lung during the next decade.[148]

The severity and frequency of the disease led to an intensive search for the gene. The gene was mapped to 7q31 (long arm of chromosome 7, banding region 31) in 1985 and was subsequently cloned in 1989.* The CF gene is extremely large, containing 27 exons and producing a transcript of approximately 6.5 kb. It codes for the CF transmembrane conductance regulator protein (CFTR) of 1480 amino acids. CFTR consists of two repeated motifs, each containing six hydrophobic transmembrane domains and one hydrophilic intracellular nucleotide-binding fold connected by a highly charged regulatory domain site.[481] The molecule is located within the lipid bilayer, predominantly at the apical membrane of secretory epithelial cells where it serves as a cyclic adenosine monophosphate (cAMP)–activated chloride ion channel to regulate chloride ion conductance.[15,44] In addition to chloride conductance, the molecule is involved in transport of sodium, potassium, and ATP from the intracellular compartment to the extracellular surface.[515,552] A routine sweat chloride concentration determination is considered necessary for the diagnosis of CF (>60 mmol/L in childhood; >40 mmol/L older than 15 years), although some patients with *CFTR* mutations may have borderline or even normal results.[112,147,200,257,544] These atypical patients may have only congenital bilateral absence of the vas deferens (CBAVD), pancreatitis, pulmonary disease, or nasal polyps. Thus although the diagnosis of CF can easily be made in patients with characteristic clinical features and abnormal sweat chloride concentrations, in patients with atypical presentation, mutations in the *CFTR* gene cannot be excluded without complete sequence analysis of the gene. The wide clinical diversity among CF patients in part is because of varying effects on the CFTR protein caused by more than 1000 mutations identified in the *CFTR* gene thus far.[126] However, it is also possible that the "nonclassic" CF phenotype is caused by factors other than mutations in the *CFTR* gene.[222]

Since CF is an autosomal recessive disorder, the CF patient must have two mutant *CFTR* alleles to develop the disease. Some mutations are "private" and unique to a family, and others may be common among CF patients. Patients will be homozygous with two copies of the same mutation or will represent a compound heterozygote with one copy of one mutation and one copy of a second mutation. Although the type and location of the mutation vary in their effect on *CFTR* and ultimately affect the phenotype of the patient, environmental factors and less characterized modifier genes also appear to be important in modulating the CF disease phenotype.* The *CFTR* genotype and clinical phenotype are most closely related for pancreatic involvement and least closely related for pulmonary manifestations of the disease.[152,652] Idiopathic juvenile patients with chronic pancreatitis have almost five times the expected carrier frequency of *CFTR* mutations, perhaps suggesting that *CFTR* carriers are predisposed to pancreatitis in the presence of other undefined pathogenetic factors, or perhaps these represent atypical patients with CF whose second gene mutation was not identified.[579] Further, although CBAVD is considered the primary congenital form of CF, most patients with CBAVD do not have two *CFTR* mutations[112]; only 19 of 102 patients had two detectable *CFTR* mutations, and 54 patients had only one detectable *CFTR* mutation.[112] Interestingly, 34 of these 54 (63%) had a rare DNA variant in intron 8 (called 5T, a sequence of five thymidines) in their second allele that is present in <5% of the general population. When present, the 5T variant affects the efficiency of exon 9 splicing and without exon 9, the chloride channel is

*References 300, 306, 409, 481, 490, 581.

*References 4, 90, 149, 213, 314, 497, 505, 509, 653.

not functional. In 29 CBAVD patients, no *CFTR* mutations were identified, but 7 (24%) had the 5T variant. Thus in CBAVD, the 5T variant allele is present and in *trans* (on the opposite allele) with a second *CFTR* mutation or is associated with the more common 7T allele when it is in *cis* (on the same allele) with *CFTR* mutation R117H (i.e., with R, arginine, in place of H, histidine, at amino acid 117). Interestingly, if the 5T allele is in *cis* with mutation R117H, it is associated with a classic CF phenotype rather than CBAVD.[301]

The types of mutations in *CFTR* can illustrate the association of the genotype with the phenotype. Mutations can be divided into five classes. Patients with class 1 mutations have defects in protein production, and class 2 mutations are associated with defective processing of CFTR. In both cases, CFTR trafficking to the cell membrane does not occur, and both class 1 and class 2 mutations are typically associated with a severe phenotype. Class 3 and 4 mutations have CFTR expression at the cell membrane, but channel activity is reduced. Class 3 mutations can be associated with a more severe phenotype and result from defective regulation, and class 4 mutations can be mild and result from defective conduction. Class 5 mutations are associated with abnormal splicing of the *CFTR* messenger ribonucleic acid (mRNA) and may be associated with a severe phenotype (621 + 1G>T) or a mild phenotype (2789 + 5G>A). The most common mutation, deltaF508, seen in about 70% of CF chromosomes in Caucasians of Northern European descent, affects processing of CFTR and prevents its trafficking to the apical membrane.[111] Prevalent mutations G542X and W1282X cause premature translation termination and thus truncation of the protein.[237] The frequently observed mutation G551D results in CFTR that reaches the apical membrane but that improperly regulates the chloride channel.[623]

DNA testing for the identification of *CFTR* mutations is performed for a variety of reasons (Box 40-1). DNA testing is performed to confirm the diagnosis of disease in patients with equivocal sweat chloride results or in instances when insufficient material is collected. Alternatively, in the known CF patient, mutation analysis can be requested to help predict the prognosis since some genotype-phenotype correlations exist. At the same time, identifying the mutations segregating in a family enables preimplantation diagnosis or prenatal testing for subsequent pregnancies and carrier or diagnostic testing for other at-risk family members. Similarly, state-sponsored newborn screening programs have detected infants with CF and at the same time have identified at-risk family members and enabled genetic testing.[626] In addition, newborn screening allows for early diagnosis and intervention of patients, which has been associated with reduced severity of lung disease and increased survival.[218,619] Some families referred for prenatal CF testing have no family history of CF. Rather, in these families, hyperechogenic bowel was diagnosed in the fetus on routine ultrasonography. In one study of 209 fetuses, 7 were subsequently given the diagnosis of CF, which is about 84 times the estimated risk of CF in the general population.[394]

The most challenging and controversial DNA testing for CF is carrier screening for preconception and expectant couples. Carrier screening in these circumstances was recommended in October 2001 by the American College of Obstetricians and Gynecologists (ACOG) in conjunction with the American College of Medical Genetics (ACMG).[12] With the heterogeneity of *CFTR* mutations, testing for more than 1000 mutations in this population would be a daunting task. For this reason, a core panel of 25 mutations was proposed as a minimum standard for CF carrier screening. The mutations initially proposed included those with an estimated prevalence of at least 0.1% of CF mutant alleles; this yields a CF carrier detection rate of about 88% for non-Hispanic Caucasians.[12,220] Slight variations in the reported frequencies of these mutations in nonHispanic Caucasian alleles have recently been described, but the overall detection rate remains at about 88%[438] (Table 40-1). The intent of the screening panel was to identify individuals at risk for classical CF, not CBAVD, and thus it is recommended that the 5T and/or 7T or 9T status be evaluated only in the presence of mutation R117H.

The standard of care recommended by the ACOG is to offer CF testing to preconception or expectant couples, a very large group of people. The social and technical issues surrounding this testing are complex. Various methods are commercially available to reduce the number of laboratories performing "home brew" assays, and standards and guidelines for *CFTR* mutation testing have been proposed[477] (Figure 40-1 and Color Plate 7). Further standardization for reporting of these complex results has been recommended, although adherence to these standards is not ideal.[17,220]

Social issues associated with population screening for this genetic disease are in part rather specific to this program (such as the enormous number of mutations in this huge gene), but many others are illustrative of issues that surround genetic testing in general. The issues surrounding this program include: (1) the inability to detect CF carriers with *CFTR* mutations other than the 25 included in the screening

TOTAL	88.40

*Frequencies represent the "average" frequency of the mutation as determined from the comparison of two data sets by Palomaki et al.[438]

panel, (2) the need for appropriate genetic counseling of patients before their consenting to the analysis, (3) the need for proper understanding of the possibility of a false-negative result, (4) stigmatization of being a "carrier" of a genetic disease, (5) threats to confidentiality of results, (6) effects on health insurability, and (7) possible increase in the number of abortions following the identification of previously unknown affected fetuses. In addition to these social and/or ethical issues, opposition to this screening panel has also arisen over the set of mutations included in the panel because those currently selected underrepresent the mutations found in minorities.[165,201,249,253-254] It is likely that mutations in the *CFTR* screening panel will change as carrier screening evolves and the program is critically evaluated.[548-549]

Hereditary Hemochromatosis

Hereditary hemochromatosis (HH) is an autosomal recessive disorder of iron regulation that can result in excess iron deposition in otherwise healthy tissue. Affected individuals can absorb approximately 3 to 4 mg of iron per day compared with the normal rate of 1 to 2 mg per day. Symptoms associated with this disease occur during mid to late adulthood, but the diagnosis of HH is often delayed, because the early symptoms of weakness, lethargy, joint pain, and abdominal pain are nonspecific. Complications of the disease include hepatic cirrhosis, diabetes mellitus, hypopituitarism, hypogonadism, arthritis, and cardiomyopathy.[29,458,641] The incidence of the disease is estimated to be about 1 in 200 to 400, making HH one of the most common genetic disorders known. However, the phenotypic expression of the disease is dependent on other genetic and environmental factors. The disease is more common in men than women presumably because of the protective effect of iron loss during menstruation and pregnancy. In addition, although regular blood donation is protective against HH, increased alcohol consumption, dietary iron, or vitamin C, an enhancer of iron uptake, increases the likelihood of symptoms in the presence of an affected genotype.[459] Laboratory testing for hemochromatosis most often includes determination of transferrin saturation [(serum iron/total iron binding capacity) × 100] and serum ferritin with a saturation >55% to 60% considered abnormal for men, >45% to 50% abnormal for women, serum ferritin >400 μg/L (400 ng/mL) abnormal for men, and >200 μg/L (200 ng/mL) abnormal for women. These tests may be ordered singly or in combination. Subsequently a liver biopsy often follows to determine the amount of stainable iron and the degree of injury.[635] Management of the disease includes therapeutic phlebotomy and dietary avoidance of medicinal iron, mineral supplements, excess vitamin C, and uncooked seafoods.[39]

In 1976 Simon et al reported an association of human leukocyte antigen (HLA)-A3 and HLA-B14 antigens with idiopathic hemochromatosis, which suggested that the HH gene was located near the major histocompatibility complex (MHC) on chromosome 6p (short arm of chromosome 6).[409,532] Classic genetic studies confirmed linkage of the HH gene to the HLA locus, and in 1996 Feder et al cloned the HH gene, *HFE*.[172,288,321] Although *HFE* remains the primary gene associated with hemochromatosis, other genes have been mapped or cloned that are associated with dominantly inherited hemochromatosis (*SLC11A3, ferroportin1, and H-ferritin*) and with juvenile and rare autosomal recessive (*TFR2*) forms of hemochromatosis. Additional genes associated with iron metabolism likely exist.*

The *HFE* gene protein, HFE, encodes a β_2-microglobulin-asociated protein with structural resemblance to MHC class I proteins. The *HFE* gene contains seven exons spanning about 12 kb, and the 4.1 kb mRNA is widely expressed with some suggestion of higher expression in the liver and intestine, major sites of iron metabolism in the body, and to

*References 97, 298, 424, 489, 496, 617.

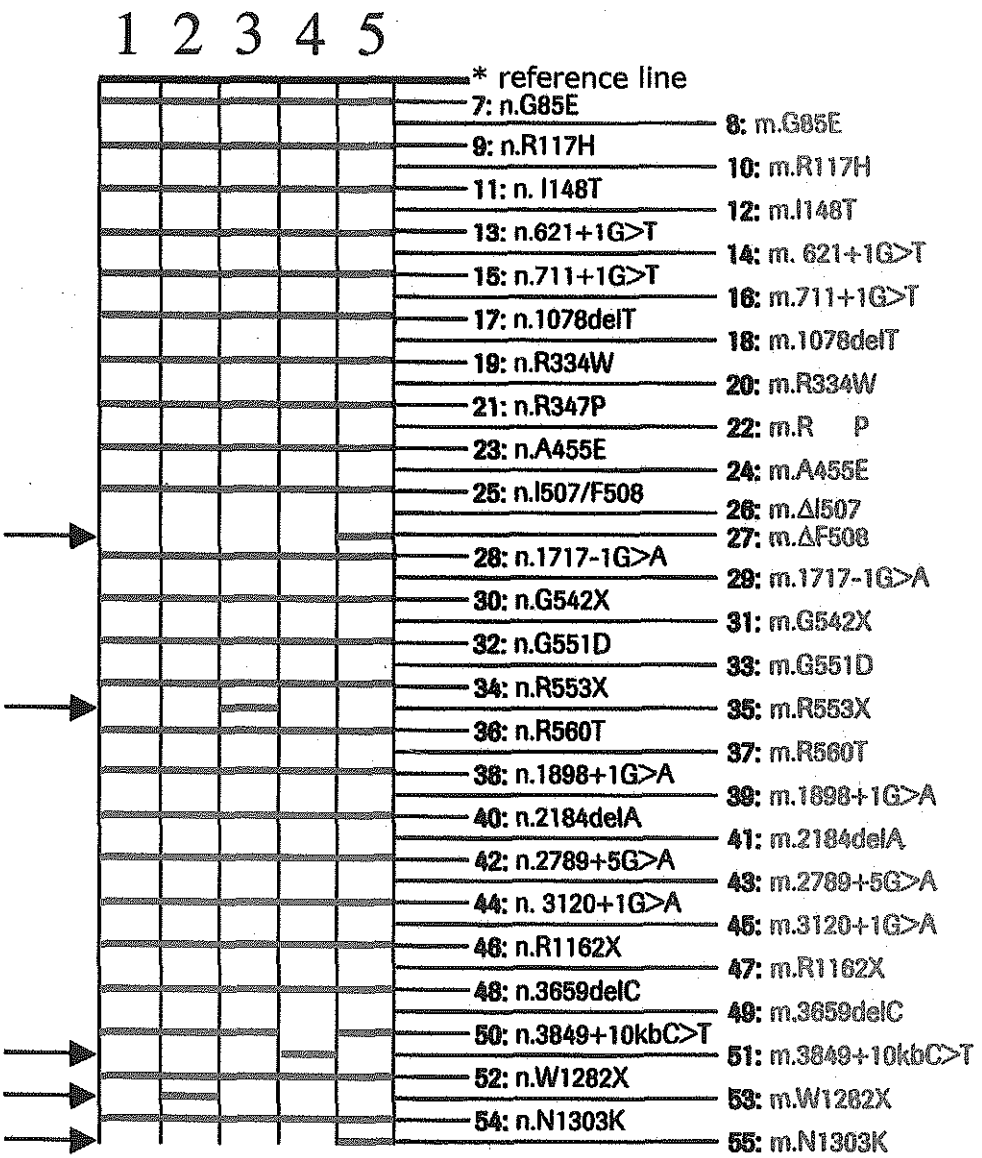

Figure 40-1 CF mutation-detection assay CF Gold 1.0 developed by Roche Diagnostics Corp. Thirty to 45 ng of patient DNA is amplified in a multiplex amplification reaction. Amplicons are denatured and hybridized to membrane-bound oligonucleotide probes specific for 25 normal (n) and corresponding mutant (m) alleles. Lane 1 represents the pattern obtained from patient DNA in which none of the 25 common mutations is present; bands detected correspond only to normal alleles. Lane 2 represents the pattern obtained from patient DNA in which mutation W1282X is present in one allele, since bands corresponding to both nW1282X and mW1282X are present. In lane 3, mutation R553X is present in one allele since bands corresponding to mR553X and nR553X are present. Lanes 2 and 3 could represent CF carriers or could represent DNA from patients with CF for whom only one of their two mutations is identified. In the latter case, the second disease-causing mutation must be a mutation other than one of the 25 represented in this panel. Conversely, lane 4 represents patient DNA in which two copies of mutation 3849 + 10kbC>T are detected. Note that no band corresponding to n3849 + 10kbC>T is present. Lane 5 represents DNA from a CF patient who is a compound heterozygote with mutation delta F508 present on one allele and mutation N1303K present on the second mutant allele. Detection of 5, 7, or 9 T polymorphism in intron 8 has not been determined in these patients but can be performed by this assay. The strip contains oligonucleotide probes for the determination of this polymorphism in patient DNA above the reference line. However, before testing, this part of the strip is removed and is only performed as a reflex test if mutation R117H is detected. (See Color Plate 7.)

a lesser degree in the brain.[172] Normal HFE binds to the transferrin receptor and reduces its affinity for iron-loaded transferrin.[173,326,504] Interestingly, although HFE is widely expressed in the gastrointestinal tract, the most abundant immunohistochemical staining for the protein is in the crypt enterocytes, where it has a distinct intracellular localization suggesting that its function is to sense the level of body iron stores and regulate, rather than directly participate in, iron absorption.[439,614] *HFE* knockout mice exhibit profound abnormalities in iron homeostasis and likewise have significantly decreased iron uptake from the plasma by the duodenum.[578,651]

A founder effect, suggested by linkage disequilibrium between HLA haplotypes and the *HFE* gene, was confirmed in two studies by the identification of homozygosity for a common mutation, G-to-A base pair substitution, in 148 of 178 (83%) and 121 of 147 (82.3%) HH patients.[61,172] This mutation results in a cysteine-to-tyrosine substitution at amino acid 282 (C282Y) in HFE and disrupts disulfide bridges required for normal interaction with β_2-microglobulin on the cell surface and allows for high-affinity transferrin binding to the uncomplexed transferrin receptor.[172-174] The allele frequency of this mutation is 0.05 in Caucasians, 0.01 in Hispanics, and as low as 0.0067 in African Americans.[454] Although carriers of this mutation have been reported to have a twofold increased risk for acute myocardial infarction compared with noncarriers, they do not have higher transferrin saturation or ferritin than C282Y noncarriers.[384,584]

A second base substitution of C-to-G in exon 2 and resulting in a histidine (H) to aspartic acid (D) substitution at codon 63 (H63D) has been identified in a higher percentage of C282Y-negative HH patients than would be expected based on the frequency of this mutation in the population.[172] This mutation is observed in 89% of HH chromosomes that do not have mutation C282Y compared with a frequency of 15% to 17% in Caucasian control *HFE* genes.[172,454] HFE, with this alteration, is expressed at the cell surface, but its interaction with the transferrin receptor is altered, resulting in more iron deposition within the cell.[173,615] The frequency of mutation H63D is lower in African Americans (0.026) and Hispanics (0.10).[454] Mutation H63D is associated with an increased risk of developing a mild form of hemochromatosis, but appears to have little effect for causing disease when inherited by itself (wild type and/or H63D), which represents 2.5% of HH chromosomes, or when two copies of the mutation are inherited (H63D/H63D), which is seen in 1.4% of HH patients.[351] Although many compound heterozygotes (C282Y/H63D) in the general population are asymptomatic, H63D may contribute to disease when inherited with mutation C282Y since 4.5% of HH patients have this genotype, although interestingly, these patients display variability in liver histological findings and iron indices.[59,287,296,351,512]

More recently a third common mutation in the *HFE* gene has been reported that is associated with a mild form of hemochromatosis.[25,264,397] This A-to-T mutation results in a serine-to-cysteine substitution at codon 65 (S65C) in exon 2 and is in close proximity in the gene to the previously described H63D mutation. In one study, mutation S65C was detected in 2.49% of normal controls yet was identified in 10 of 128 (7.8%) of HH chromosomes that coded for neither C282Y nor H63D.[397] Thus although C282Y is the primary mutation in *HFE* associated with HH, compound heterozygotes C282Y-H63D and C282Y-S65C have an increased risk of developing HH, thus suggesting their role in the development of HH.

DNA analysis of the *HFE* gene is done using a variety of methodologies and in most laboratories includes testing for mutations C282Y and H63D (Figure 40-2). Once *HFE* mutation analysis has confirmed the cause of HH in the patient, transferrin saturation (TS), serum ferritin, and DNA testing of at-risk family members can identify those who may benefit from earlier treatment and dietary restrictions.[88]

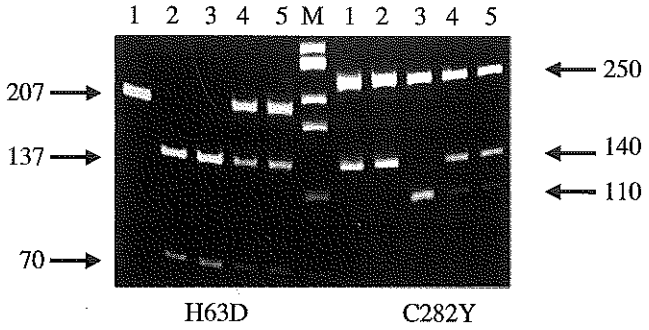

Figure 40-2 Detection of mutations H63D and C282Y in the *HFE* gene. Patient DNA is amplified by PCR using oligonucleotide primer pairs that flank either mutation H63D or C282Y, respectively. For detection of mutation H63D, 207 bp PCR products are digested with restriction endonuclease *BclI* and subjected to electrophoresis on a 5% polyacrylamide gel *(left)*. Mutation H63D results from a C-to-G base substitution and destroys a *BclI* site thereby preventing digestion of 207 bp fragments into 137 bp and 70 bp fragments. Detection of mutation C282Y uses digestion of 390-bp amplified products with restriction endonuclease *RsaI* and electrophoresis on a 5% polyacrylamide gel *(right)*. Mutation C282Y results from a G-to-A base substitution and creates an *RsaI* site within the amplicons cleaving 140-bp fragments to 110-bp and 30-bp fragments. In patient one *(lanes 1)*, the H63D-specific 207-bp amplification products are not digested with *BclI* to yield wild-type bands of 137 bp and 70 bp, thereby indicating that the restriction site has been lost in both alleles. Conversely the C282Y-specific amplicons from patient one yield exclusively wild-type bands of 250-bp and 140-bp fragments. Genotype for patient one is interpreted as mutation H63D, wild-type C282Y on both alleles. Genotype for patient two *(lanes 2)* is wild-type H63D, wild-type C282Y on both alleles. Genotype for patient three *(lanes 3)* is wild-type H63D, m C282Y on both alleles. Patient four *(lanes 4)* is a compound heterozygote with mH63D, wild-type C282Y on one allele and wild-type H63D, mC282Y on the second allele. *Lanes 5* represents control DNA heterozygous for mutations H63D and C282Y.

HH is illustrative of common problems in screening for genetic disorders. Since HH is a common disorder with clinical symptoms that can be prevented with easy and inexpensive early intervention, population-based screening for HH has been considered.[92,116] If DNA-based testing were to be used in an attempt to identify HH patients, stigmatization and discrimination in *HFE*-positive patients could result. Moreover, because of incomplete penetrance, many people with mutations will neither have nor ever develop iron overload.[5,60,433] Phenotypic measurements of transferrin saturation or serum ferritin could be more appropriate than genotypic studies for population-based screening for HH, but these results can also be misleading since iron overload can occur from a host of other conditions unrelated to hemochromatosis and mutations in *HFE*.[635] For these reasons and others, national population-based screening programs have not been implemented. However, a comprehensive, multicenter, 5-year, multiethnic study involving 100,000 adults is in progress to evaluate the prevalence, genetic, and environmental factors associated with HH and the personal and societal impact of screening and diagnosis. The information obtained from this Hemochromatosis and Iron Overload Screening (HEIRS) study will assist in determining policy regarding the feasibility, logistics, and associated benefits of population screening.[368]

Carbamyl Phosphate Synthetase I Deficiency

Carbamyl phosphate synthetase I (CPSI) deficiency is an autosomal recessive inborn error of metabolism with an estimated incidence of about 1 in 62,000 in the United States to as low as 1 in 800,000 in Japan.[85,405] The frequency of the disease may actually be higher in regions of the world with a higher percentage of consanguineous matings, and reported frequencies do not account for the undiagnosed neonates that die in the first few days of life. The affected newborn appears clinically normal but within the first 24 to 72 hours develops vomiting and lethargy, and as blood ammonia levels continue to rise, coma and death are imminent unless treatment is initiated immediately. Although a delay in diagnosis and treatment is associated with a worse prognosis, the disease is rare, the symptoms are rather nonspecific, and diagnosis is often delayed. The condition can be first interpreted as sepsis. Once the diagnosis is made, sodium benzoate and sodium phenylacetate can be started,[554,582] and hemodialysis may be required to further reduce ammonia levels and prevent irreversible brain damage and death arising from cerebral edema.[163,554] Prospective treatment in at-risk patients to prevent hyperammonemia improves neurological outcome.[355,654] Laboratory findings include increased plasma ammonia; low plasma urea; decreased or absent plasma citrulline and arginine; normal urine orotic acid; and normal urine organic acids.[543] The diagnosis is confirmed by a liver biopsy for measurement of CPSI activity. In most patients, CPSI enzyme activity less than 20% of controls is consistent with CPSI deficiency, and activity less than 5% results in neonatal presentation. However, a few patients have been reported with partial CPSI activity that was associated with late or adult presentation.[95,269,342,508,636] The chronic phase of the disease is treated with a nitrogen-restricted diet, citrulline, and chronic sodium phenylbutyrate to reduce the blood ammonia.[57] Management of this urea cycle disorder is complex and is most effective with immediate intervention and a multidisciplinary effort.[554] Liver transplantation can be an effective form of treatment.[629]

The *CPSI* gene is mapped to 2q35, spans >120 kb, comprises 38 exons, and consists of a 123-nucleotide 5′-untranslated region, an open reading frame of 4500 nucleotides, and 1123 nucleotides in the 3′-untranslated region.[409,555-556] Exons range in size from 56 to 260 bp in length, and introns range from 415 to 21,160 bp.[556] The *CPSI* gene encodes a 165 kD proenzyme that is transported into the mitochondria, where it is cleaved into the functional 160 kD form.[239] CPSI is present in the mitochondrial matrix of hepatocytes and epithelial cells of the intestinal mucosa.[502] CPSI catalyzes the first step of the urea cycle by converting ammonia and bicarbonate to carbamyl phosphate.[500] Through a series of enzymatic reactions, the toxic ammonia molecule is converted to the nontoxic water-soluble urea containing two amino groups, which is excreted as urine. In the absence of CPSI or any of the other urea cycle enzymes, a hyperammonemic crisis ensues, and associated neurological tissue destruction and/or death occurs.

In contrast to DNA testing for hereditary hemochromatosis, which is a widespread disorder with only three common mutations, or CF, a frequent disease with more than 1000 mutations, CPSI deficiency represents a rare disorder with no common mutations. Rather, heterogeneous mutations throughout the gene have been described including missense, deletion, insertion, and splicing mutations.[24,177,272,472,553] Heterogeneous mutations for a rare disease make clinical testing for CPSI deficiency challenging. With a relatively low volume of specimens received annually, a clinical laboratory cannot batch specimens to improve the efficiency of testing, because turnaround times would not be acceptable. Thus it is not feasible for a clinical laboratory to sequence the very large *CPSI* gene in every family to identify the private mutations segregating in that family. For these reasons, DNA testing in a clinical laboratory for CPSI deficiency most often involves indirect testing or linkage studies using highly polymorphic microsatellite repeat markers (Figure 40-3 and Color Plate 8). Further DNA testing is not used to make or confirm the diagnosis, but rather to determine the haplotype of the microsatellite markers flanking the abnormal *CPSI* genes segregating with the disease in each family. Once this has been determined, haplotype analysis can be performed on a subsequent at-risk fetus to determine its status with regard to CPSI deficiency.

To initiate these studies, once the diagnosis of CPSI deficiency has been confirmed by enzymatic studies on the affected child, or is strongly suspected from abnormal laboratory results, DNA specimens are collected from the parents

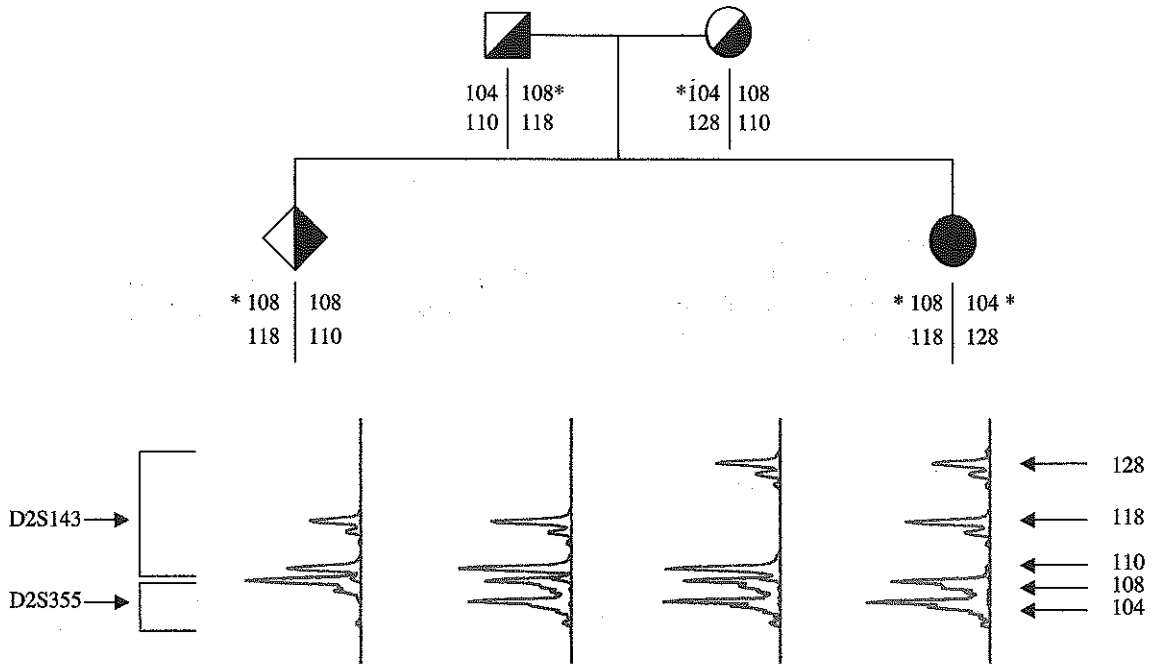

Figure 40-3 Electropherograms illustrating prenatal DNA-linkage studies on a family with CPSI deficiency D2S355 and D2S143 represent dinucleotide markers 4 centimorgans 5′ (D2S355) and 3 centimorgans 3′ (D2S143) to the *CPSI* gene, respectively. DNA samples from the affected child, parents, and fetus are amplified by PCR using oligonucleotide primer pairs specific for each marker, with one primer of each pair labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel on an ABI 377 DNA sequencer and analyzed using GeneScan software 3.1b3. The maternal haplotype donated to the affected child is 104,128, indicating that the mother's 108,110 allele is not linked to an abnormal *CPSI* gene. The paternal allele donated to the affected child is 108,118, indicating that the father's 104,110 allele is in repulsion with CPSI deficiency. The maternal allele donated to the fetus is 108,110. This allele is not linked to an abnormal *CPSI* gene. The paternal allele donated to the fetus is 108,118. This allele is linked to an abnormal *CPSI* gene. These results indicate that the fetus is a carrier of CPSI deficiency but is not affected. (See Color Plate 8.)

and the affected child. If the affected child died before collection of a peripheral blood sample, paraffin-embedded autopsy material can be submitted for analysis. Within days, *CPSI*-linked DNA markers for the family are analyzed, markers for which the family is informative are identified, and the accuracy of future prenatal linkage studies is determined. When the family ultimately requests future prenatal testing, either chorionic villus tissue or cultured chorionic villus tissue or amniocytes from the fetus are submitted for analysis. Within a few days, the fetal DNA is tested with the DNA markers for which the family is informative, and a diagnosis regarding the CPSI deficiency of the fetus is known. In most instances, the accuracy of the results approaches 99%.

Although considered highly accurate and rapidly applicable to all families regardless of the CPSI mutation, linkage studies can be problematic.

- First, linkage studies cannot determine the diagnosis of the affected child, but rather rely upon additional laboratory testing and clinical findings to identify this disease in the patient. An *accurate diagnosis* of CPSI deficiency is essential before initiating DNA studies. For example, if the diagnosis in the affected child is incorrect and a disease-causing mutation is present in a gene other than *CPSI*, then linkage studies using DNA markers flanking the *CPSI* gene to predict the status of an at-risk fetus are totally irrelevant and will lead to erroneous conclusions. In such cases, a second child inheriting the same *CPSI* haplotypes from each parent may be misinterpreted as affected; the pregnancy may be terminated when, tragically, the fetus was normal. Alternatively, if the second child inherits different *CPSI* haplotypes from each parent, the fetus may be misinterpreted as being normal when in fact the fetus may have inherited the same unknown disease-causing mutation(s) as the previously affected child with an inaccurate diagnosis of CPSI deficiency.
- A second requirement for linkage studies is that the family structure must be accurately reported. Since the microsatellite repeat markers used in the analysis are highly polymorphic, cases of *alternative paternity* are likely to be detected. Nonetheless, if the father of the affected child shared similar haplotypes with the father of the fetus,

misinterpretation of the results would occur. This scenario could result in the termination of a normal pregnancy.

- Third, because of the chance of *genetic recombination* between the *CPSI* gene and the linked, flanking polymorphic markers, the possibility of recombination exists and with that the possibility of an incorrect diagnosis for the fetus. This could result in the birth of a second affected child despite the fact that the haplotypes of the two affected children differ, or a normal pregnancy may be terminated if, through genetic recombination, the fetus shares the same haplotype but is unaffected.
- Last, although highly polymorphic, the possibility exists that one or both parents are *not informative* (i.e., heterozygous) for one or more of the DNA markers thereby preventing prenatal studies on future at-risk pregnancies or compromising the accuracy of future prenatal results.

Although less commonly performed now, prenatal testing for CPSI deficiency can be performed by measuring CPSI activity in tissue from a fetal liver biopsy specimen.[399,519,644]

Autosomal Dominant Diseases

In autosomal dominant conditions, a single abnormal allele is sufficient to cause disease despite the presence of a normal allele. An individual with an autosomal dominant disease may have inherited an abnormal allele from an affected parent, or alternatively the mutant allele may have risen de novo as a new mutation during gametogenesis in an unaffected parent. The disease-causing gene is on one of the autosomes (1 to 22) and not on a sex chromosome (X or Y). An affected individual possesses a 50% risk of donating the mutant allele to an offspring. Different mutations within the gene have varying effects on the protein so that affected patients can have variability in clinical expression of the disease. In some instances, known mutant gene carriers have no clinical symptoms of the disease, a phenomenon referred to as reduced penetrance, yet possess a 50% chance of having an affected child. Differences in phenotypic expression of the disease are most likely explained by the effect of other genes (modifier genes) and/or environmental influences. In pedigrees illustrating autosomal dominant inheritance, both males and females are affected, and male-to-male transmission is observed.

Achondroplasia

Achondroplasia is the most common form of human genetic dwarfism and is inherited as an autosomal dominant trait with complete penetrance. It is characterized by short-limbed dwarfism (rhizomelic form), macrocephaly, frontal and biparietal bossing, bowing of the lower extremities, and normal intelligence. Infants with this disease can die within the first year of life from central apnea caused by compression at the craniocervical junction; homozygous disease is most often lethal.[211,415,444] Children undergoing surgical decompression of the craniocervical junction have decreased mortality and demonstrate improvement in neurological function. The mean standard deviation (SD) adult height is 131 (5.6) cm for men and 124 (5.9) cm for women. The life expectancy is about 10 years less than that for the general population.[246] During the first 5 years of life, affected children are at risk of death from compression of the brainstem and/or the upper cervical spinal cord. Deaths in adults between 25 and 54 years of age are most often attributed to cardiovascular problems. Achondroplasia has an incidence of about 0.5 to 1.5 per 10,000 births and has been reported in individuals from different races and ethnic groups.[434]

More than 90% of patients are born to parents of normal height. These patients represent sporadic cases arising from new mutations, a phenomenon associated with advanced paternal age.[415,630] However, in one unusual report, two siblings with achondroplasia born to unaffected parents were a result of germline mosaicism from the mother since, although she had no clinical features of achondroplasia, a mutant allele was detected in DNA extracted from her peripheral blood.[252] In a second remarkable case, two affected siblings sharing a 4p haplotype derived from their unaffected father were born to normal-sized parents, suggesting that either two de novo, independent, sporadic events had occurred, or paternal gonadal mosaicism was present.[540] This "paternal effect" has been thought to occur because of lifelong spermatogonial stem cell divisions and thus an increase in production of mutant sperm as the male grows older.[124] However, recent data generated from examining sperm DNA from donors of different ages did not illustrate an exponential increase in mutation with age, indicating that sperm mutation frequency cannot explain an effect of paternal age in achondroplasia.[573]

The gene for achondroplasia was mapped to the telomeric region of chromosome 4p (4p16.3) in 1994 using linkage studies on multigenerational families.[186,409,604] Subsequently the fibroblast growth factor receptor 3 gene (*FGFR3*), mapped to this region and previously considered as a candidate gene for Huntington's disease (HD), was evaluated as a candidate gene for achondroplasia and reported to have mutations in patients with achondroplasia.[527,570] The *FGFR3* protein product, FGFR3, contains three extracellular immunoglobulin-like domains, a single transmembrane domain, and an intracellular tyrosine kinase domain.[294] FGFR3 is a tyrosine kinase receptor, which when bound to 1 of 23 fibroblast growth factors (FGFs) coupled with heparin sulfate–bearing proteoglycans on the cell surface, induces dimerization of receptor monomers, activates tyrosine kinase activity, and promotes phosphorylation of key tyrosine residues in the cytoplasmic domain, which in turn induces multiple signaling pathways.[271,564] Precisely which FGFs serve as ligands for FGFR3 is not known, and FGFR3 may use different FGFs at different stages of development and at different locations of the growth plate. The target genes for FGFR3 are not well characterized, but FGFR3 is thought to negatively regulate chondrocyte proliferation and differentiation.[117,139]

The primary mutation in achondroplasia results in a defect in internalization and degradation of the mutant receptor. Thus it is retained on the cell surface and has uncontrolled and prolonged activation in chondrocytes.[388] Hence, chondrocyte maturation and terminal differentiation are inhibited. Following the discovery of the association between achondroplasia and *FGFR3* mutations, other similar gain-of-function mutations at other sites within this gene have been identified as the cause of less common forms of dwarfism, including thanatophoric dysplasia types I and II and hypochondroplasia.[49-50,463,494,566]

In the original report identifying the *FGFR3* gene as the cause of achondroplasia, 15 of 16 patients had a G-to-A transition mutation at nucleotide 1138 (G1138A), and the only patient that did not have this mutation instead had a G-to-C transversion mutation at the same position (G1138C).[527] Both mutations result in a glycine-to-arginine substitution in the transmembrane domain of FGFR3 at codon 380. The frequency of the G-to-A transition mutation at codon 380 in achondroplasia patients is well documented.[48,493] This base pair may be prone to mutation, because a cytosine residue in a CpG dinucleotide is known to be a hot spot for transition mutations.[36,64,151] If the cytosine residue is methylated (i.e., as 5-methylcytosine), it can spontaneously deaminate to thymine to introduce the change from a G:C base pair to an A:T base pair in subsequent replications of DNA. Since >98% of *FGFR3* mutations causing achondroplasia are G1138A, and about 1% are G1138C, DNA testing includes direct mutation analysis for both mutations. Testing can be performed postnatally to confirm the diagnosis of achondroplasia. In addition, prenatal DNA testing may be requested by unaffected couples with an affected child representing a sporadic case, although the risk for germline mosaicism is considered low, and their risk of a second affected child is minimal. Pregnancies involving mating between two affected individuals are not uncommon. Prenatal DNA testing can be requested by these couples who have a 25% chance of having a child homozygous for this condition. This presents difficult choices for the couple. In one study, attitudes of affected individuals and relatives toward abortion based on prenatal diagnosis indicated that if the fetus was determined to be homozygous for this condition, 40% would consider termination compared with 41% that would not; 19% were unsure of what they would do.[210] In this same study, if the fetus was heterozygous for a mutation causing achondroplasia, 5% would consider termination and 86% would not; 8% were unsure what they would do. Lastly, if the fetus was determined to be normal and not to have received a mutation causing this disease, 90% responded that they would not consider termination of the pregnancy but 3% would; 6% were unsure of what their decision might be.

Charcot-Marie-Tooth Disease

Charcot-Marie-Tooth (CMT) disease, sometimes referred to as hereditary motor and sensory neuropathies (HMSN), refers to a genetically heterogeneous group of hereditary neuropathies characterized by chronic motor and sensory polyneuropathy and demonstrating all patterns of mendelian inheritance.[54,69]

The most common form of CMT, type 1A, is one of the most common autosomal dominant disorders in man, with an estimated incidence of 1 in 2500. This disease is characterized by progressive distal muscle atrophy and weakness, depressed or absent deep tendon reflexes, high-arched feet, decreased nerve conduction velocity (generally <35 to 40 m/s), and nerve demyelination as visualized on biopsy specimens. The age of onset is within the first decade of life in 50% of patients and before the age of 20 in 70% of patients.[65] However, despite a common genetic abnormality, phenotypic manifestations of the disease are variable even within the same family, suggesting the influence of environmental factors or modifier genes at other loci.[65,330] Lastly, as in achondroplasia, the phenotype of patients who are homozygous for two abnormal CMT genes, having inherited an abnormal CMT gene from each of their parents, is more severe despite having nerve conduction velocities similar to heterozygotes or those with one abnormal allele.[551]

In studies of extended families with CMT, the gene was mapped to the short arm of chromosome 17 and specifically localized to 17p11.2-p12 (short arm of chromosome 17 between banding regions 11.2 and 12).[376,409,466,594-595] Further, some DNA markers in this region detected a duplication in the DNA of affected individuals within families and in unrelated CMT patients.[232,347] The peripheral myelin protein gene, *PMP22,* was identified as a candidate gene for CMT type 1A in 1992.[442] *PMP22* is contained within a 1.5 Mb monomer unit that is flanked by several low-copy repeat sequences.[450] A duplication of the gene is associated with disease and results from unequal meiotic crossing over caused by misalignment of homologous sequences. Breakpoints within the repeated sequences are variable between patients, but 76% occur within a 1.7 kb "hot spot" for recombination where the DNA sequences are 98% homologous.[475] The reciprocal deletion of this crossover resulting in the loss of an allele and only one copy of the *PMP22* gene is associated with a different condition, hereditary neuropathy with liability to pressure palsies (HNPP).[108] Although the vast majority of patients with CMT type 1A have *PMP22* gene duplications, point mutations have also been reported to cause disease.[484,589] Interestingly, one such mutation is the same mutation identified in the spontaneously occurring neurological mouse mutants, *Trembler-J.*

A duplication of *PMP22* results in an extra copy of the gene (altered *gene dosage*) and overexpression of the PMP22 protein, which is considered the causative event for disease. Interestingly, patients with trisomy 17p (three copies of the short arm of chromosome 17), who would have an altered *PMP22* copy number, also have clinical features consistent with CMT.[109,348] PMP22 is a 160–amino acid transmembrane glycoprotein that contains four transmembrane hydrophobic regions and two extracellular domains with the amino

and C termini exposed to the cytosol. It is predominantly localized in the compact portion of myelin.[127] PMP22 is predominantly expressed in myelinating Schwann cells of the peripheral nervous system where it is important in myelination and myelin stability and acts as a negative modulator of Schwann cell growth.[403,538,657] From studies on transgenic mice, it has been proposed that when overexpressed, PMP22 accumulates in a late-Golgi and/or plasma-membrane compartment and uncouples myelin assembly from the underlying program of Schwann cell differentiation.[422]

The *PMP22* gene duplication associated with CMT type 1A can be detected by use of Southern blot analysis, fluorescence in situ hybridization (FISH) on interphase cells, or PCR.[27,30,383,518,550] Detection of the CMT 1A duplication or HNPP deletion can be made by observing unique PCR products not seen in normal controls, which represent junction fragments formed from the recombination event between *PMP22* flanking repeated sequences.[550] Alternatively the detection of three (CMT 1A) or conversely one (HNPP) allele, rather than the expected two seen in normal control DNA following amplification of multiple microsatellite repeat markers in this region, offers another rapid and accurate use of PCR.[30,323,518] These methods are useful for clinical testing, but as a result of gene patents and exclusive license agreements for clinical DNA testing for CMT 1A, testing is available only at one laboratory in the United States.[196,332]

In families in which the duplication has been identified, testing of asymptomatic adult relatives is possible, and testing of a minor is discouraged. Prenatal testing for this nonlethal, clinically variable, adult-onset disorder would be possible but requires in-depth genetic counseling to review the ethical and psychological aspects of such studies.[55] In the suspected patient with no family history and in which no gene duplication has been identified, the risk of transmission of the disorder to their offspring is less clear. The patient could have a de novo point mutation in *PMP22* not detected or have an affected father but be unaware that the diagnosis is caused by alternative paternity; the patient could have CMT caused by an autosomal recessive or an X-linked gene or have a disorder arising from an environmental effect.

Huntington's Disease

HD is an autosomal dominant, late-onset neurodegenerative disorder with an incidence of about 1 in 10,000 in most populations of European origin. The disease is progressive and characterized by frequent involuntary, rapid movements (chorea) and dementia with a median survival time of 15 to 18 years after the onset of symptoms.[243] The mean age of onset is in the decade between 35 and 44 years, but approximately 25% of patients first display symptoms after the age of 50, and about 10% of patients have juvenile HD with the age of onset before 20 years.[243,402] In the first few years of the disease, symptoms include mood disturbances, cognitive deficits, clumsiness, and impairment of voluntary movement.[243] The next stage of the disease is associated with slurred speech (dysarthria), hyperreflexia, chorea, gait abnormalities, and behavioral disturbances including intermittent explosiveness, apathy, aggression, alcohol abuse, sexual dysfunction and deviations, and increased appetite.[183] As the disease advances, bradykinesia, rigidity, dementia, dystonia, and dysphagia are present. In the late stages of HD, weight loss, sleep disturbances, and incontinence occur.

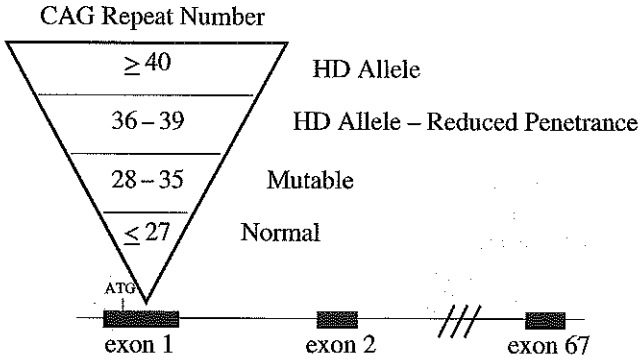

Figure 40-4 Schematic representation of the polyglutamine-encoding CAG repeat in exon 1 of the HD gene and associated alleles. A CAG-repeat number ≤27 is considered normal. CAG-repeat numbers of 28 to 35 are "mutable" and although they are not associated with an abnormal phenotype, these alleles are prone to meiotic expansion to an HD allele. CAG repeats of 36 to 39 are considered HD alleles but with reduced penetrance, indicating that both unaffected and affected patients have been reported with alleles of this size. CAG repeats ≥40 are associated with HD with complete penetrance.

In 1983 Gusella et al reported linkage between DNA marker D4S10 on the short arm of chromosome 4 and HD based on studies from a large kindred in Venezuela.[226] Subsequently, more DNA markers were identified, and the region of the genome containing the HD gene was narrowed to 4p16.3 (short arm of chromosome 4 band 16.3).* Through an international collaborative effort and 10 years after its initial localization, the HD gene, *IT15*, was cloned.[274] The molecular basis of HD was determined to be expansion of a glutamine-encoding CAG trinucleotide repeat and was subsequently confirmed in a worldwide study by the identification of expanded CAG repeat alleles in HD patients from 565 families representing 43 national or ethnic groups.[309] In this initial international study, the median CAG-repeat length was reported to be 44 in affected patients and 18 in controls. Normal CAG repeats range from 10 to 27, repeats of 28 to 35 are considered "mutable," repeats of 36 to 39 are associated with reduced penetrance of the disease, and repeats of 40 or greater are associated with HD[11] (Figure 40-4). No environmental or genetic factors associated with the penetrance of the HD are known.[499]

New mutations for HD (the presence of an affected individual in the absence of a family history) occur from expan-

*References 42, 119, 202, 352, 409, 622.

sion of CAG-mutable alleles and occur almost exclusively through expansion during paternal transmission.[208] Although mutable alleles are present in about 1% of the population, it appears that flanking DNA sequences may influence the instability of these alleles by enhancing the formation of hairpin loop structures.[114,209] In addition, single sperm analysis studies have demonstrated 11% instability (9% expansions and 2.5% contractions) in CAG repeats of 30 compared with 0.6% instability (contractions only) seen in average sized alleles of 15 to 18 repeats.[329] These studies indicated that there is an increase in instability as the repeat number increases. This concept is further supported by the observations that CAG repeats of 36 showed 53% instability, and CAG repeats from 38 to 51 had instability ranging from 92% to 99%. As in fragile X syndrome, instability of the CAG repeat is also likely to occur through replication slippage caused by formation of hairpin loop structures.[209]

The number of CAG repeats is inversely correlated with the age at onset of the disease. Patients with onset as early as 2 years of life have a repeat number approaching 100 or greater and late-onset-disease patients have repeat numbers of 36 to 39.*

The onset of symptoms occurs at progressively younger ages in successive generations of affected families, a pattern called anticipation. Anticipation is explained by meiotic expansion of the unstable CAG repeat during transmission by the affected parent, resulting in an even higher CAG-repeat number in the offspring and an earlier age of onset. In addition, although 69% of affected father-child pairs show expansion, only 32% of affected mother-child pairs demonstrate expansion. Further, <2% of maternal expansions result in a change of >5 repeats, whereas up to 21% of paternal transmissions increase by >7 repeats.[308] An increase in the CAG-repeat number is also associated with more rapid progression of disease and greater neuropathological severity in the striatum.[189,449] Interestingly, however, homozygotes with two expanded CAG-repeat alleles do not have more severe disease than heterozygotes.[309,401,625]

The HD gene protein, huntingtin (htt), consists of 3144 amino acids, is ubiquitously expressed in all tissue, and predominantly resides in the cytoplasm with lesser amounts in the nucleus.[133,227,267,575,602] In neurons, htt is associated with synaptic vesicles and microtubules and is abundant in dendrites and nerve terminals. Huntingtin interacts with multiple proteins functioning in intracellular trafficking and cytoskeletal organization, thereby suggesting its role in these activities.† Expansion of the CAG repeats results in elongation of the *N*-terminal glutamine tract and triggers the preferential loss of striatal neurons.[335]

The precise mechanism of disease progression has not been elucidated. However, expanded alleles are effectively transcribed and translated, but as a result of the increase in glutamine residues, the protein is misfolded.[510] Thus abnormal folding may result in aberrant protein-protein interaction of mutant htt with any of its protein partners and could contribute to the pathogenesis of HD. In addition, truncated fragments of mutant htt, containing the amino terminus with expanded polyglutamine repeats, accumulate to form large aggregates in the nucleus (nuclear inclusions) and in other subcellular compartments.[141,325,346] The aggregates are thought to be toxic to the cell and may also sequester proteins essential for cell viability (e.g., transcription factors) or may trigger degradation of specific factors through the ubiquitin-proteasome-dependent pathway.*

DNA testing for HD is performed by use of PCR so that the exact CAG-repeat number can be determined.[274] Soon after the initial report, it was discovered that the accuracy of determining the CAG-repeat number by PCR was compromised by the inclusion of a polymorphic CGG repeat immediately downstream from the CAG repeat. Since the CGG repeat was contained within the amplified sequence, the length of the amplicon could be altered and overestimated.[20,498] Upon this discovery, a new primer pair was identified that flanked the CAG repeat, yet excluded the problematic polymorphic CGG repeat and provided accurate assessment of the CAG-repeat number.[621] However, in contrast to earlier years when PCR involved the use of ^{32}P labeled primers for this and similar assays, currently the most common methodology for this assay involves the use of PCR with fluorescently labeled primers[609] (Figure 40-5 and Color Plate 9). In addition, guidelines for diagnostic testing by clinical labs with reference to standardization and interpretation have been proposed.[11]

Besides the technical and interpretive difficulties associated with HD testing, many ethical issues exist as well, primarily as they relate to presymptomatic testing (Box 40-2). The first policy statement on ethical issues relating to genetic testing for HD was adopted in 1989 at a joint meeting with representatives from the International Huntington Association and the World Federation of Neurology.[279] At this time, the gene had not yet been cloned, and predictive testing was performed using linkage studies; the asymptomatic patient was quoted the likelihood of inheriting the mutant allele. These tests were less than perfect and provided, at best, results in only 60% to 75% of families. Moreover, the possibility of recombination allowed erroneous predictions to occur.[244,400] In other families, living affected members were not available, or markers were not informative. Once the gene was cloned and direct mutation analysis was possible, risk assessments were reversed in a small percentage of patients.[9]

Following the cloning of the gene and the availability of direct mutation analysis, guidelines for predictive testing were reevaluated and proposed by the International Huntington Association and the World Federation of Neurology Research Group on Huntington's Chorea.[280] Direct predic-

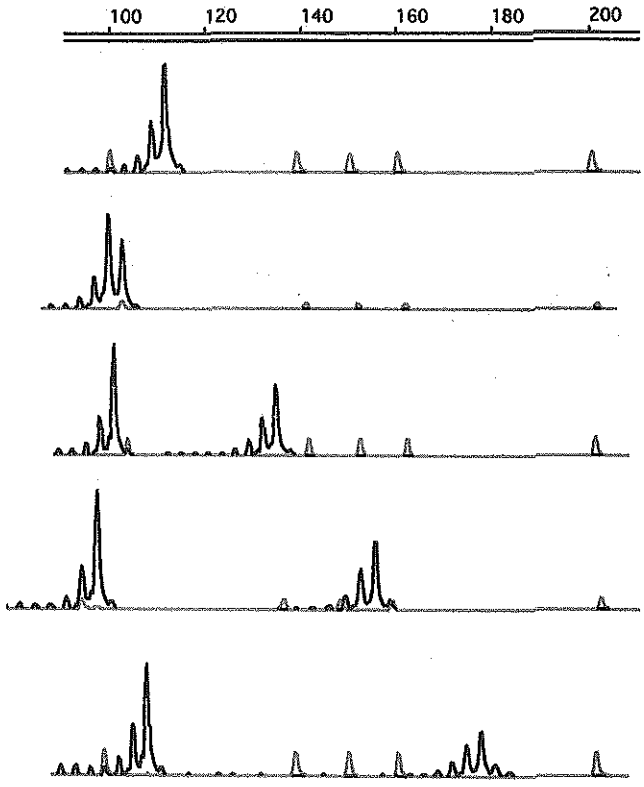

Figure 40-5 Electropherograms representing various patterns observed in patients referred for HD testing. The polyglutamine-encoding CAG repeat in exon 1 is amplified by PCR using flanking oligonucleotide primers, one of which is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel on an ABI 377 DNA sequencer and analyzed using GeneScan software 3.1 b3. Amplicons 100 bp in length contain 18 CAG repeats and flanking DNA. Patient one *(row 1, top)* has amplicons 112 bp in length and has 22 CAG repeats on both HD alleles. Patient two *(row 2)* has 97 bp and 100 bp amplicons, corresponding to CAG repeats of 17 and 18. The diagnosis of HD can be ruled out in these two patients. Patient three *(row 3)* has 97 bp and 133 bp amplicons corresponding to CAG repeats of 17 and 29. The results would not support a diagnosis of HD. However, a CAG repeat of 29 is mutable and can undergo meiotic expansion to an HD allele. Patient four *(row 4)* has CAG repeats of 19 and 38 as depicted by amplicons 103 bp and 160 bp in length. In the symptomatic patient, these results would support the diagnosis of HD. However, in the presymptomatic patient, the phenotype of this HD allele with reduced penetrance cannot be predicted with certainty. Patient five *(row 5)* has CAG repeats of 21 and 44 since amplicons 109 bp and 178 bp in length were detected. These results would confirm the diagnosis of HD. Genetic counseling regarding the implications of the DNA findings in patients three, four, and five is indicated. (See Color Plate 9.)

tive testing was preferred over linkage studies and was readily accepted by the HD community.[28] The approach used for HD has become the model for predictive testing for late-onset diseases, and similar formats have been applied to other late-onset inherited diseases, including autosomal

BOX 40-2 Ethical Issues Associated With Presymptomatic DNA Testing for HD

Patients must be 18 years of age.
The decision to proceed with testing must be voluntary and informed.
Genetic counseling regarding benefits/pitfalls of testing is required.
A support partner is needed for the patient for counseling and the testing process.
Diagnosis of HD in family should be confirmed by DNA testing before presymptomatic testing.
Psychiatric assessment of patient is necessary before testing.
Follow-up genetic counseling is recommended after delivery of results.
Discrimination by insurance carriers or employers may occur following completion of testing.
Prenatal testing of fetus is controversial; preimplantation diagnosis is available.

dominant cerebellar ataxias, and less common, dominantly inherited, fatal familial insomnia.[207,588] If an HD-causing expanded CAG-repeat allele is identified in the asymptomatic patient (≥40 years), the median age of onset in HD patients with the patient's corresponding CAG-repeat number can be quoted to the patient.[81] Predictive testing should be performed only on adults and only with informed consent. Informed consent implies that the patient has been thoroughly counseled and clearly understands both the advantages and disadvantages of knowing the results. Advantages of having this test include but are not limited to the removal of uncertainty regarding whether they have or have not inherited the mutant allele and the feeling of relief for those who have not inherited a mutant HD allele. This information can help patients appropriately plan their personal and career paths. Disadvantages of knowing this information include but are not limited to: (1) the feeling of "survivor's guilt" in those who learn that they have not inherited a mutant allele and other family members have; (2) fear from learning that they have inherited a mutant HD allele and will develop this incurable disease; (3) risk of discrimination in employment or health insurance coverage if the results are disclosed; (4) worry that they possess a 50% chance of passing this gene on to their offspring; and (5) uncertainty of developing disease if they have inherited a mutant HD allele containing 36 to 39 CAG repeats.

Importantly the guidelines indicate that the patient should be accompanied by a trusted friend or loved one throughout the counseling and testing procedure. This person can provide stability to the patient by being able to intimately speak to the patient about the situation and discuss the information shared at the counseling sessions. Most importantly, as a part of this process, the partner will be present when the results of the testing are revealed and

can provide comfort and support as needed both then and in the following days, weeks, or months. Ultimately, however, it is the patient's decision to proceed with this testing and to accept both the benefits and pitfalls of knowing this information. The patient's decision to proceed must be his or hers, without coercion from family members, clinicians, friends, or employers.

Since catastrophic events, such as suicides or attempted suicides, can follow predictive testing, a psychiatric assessment is often part of the testing protocol for the safety of the patient.[10] Before performing the mutation studies, it is important that the patient be considered mentally stable since the HD test results can precipitate depression. The results of the psychiatric evaluation can influence the time of the DNA test, postponing it until such time when the patient is considered mentally able to deal with the possibly devastating news.

If possible before testing, the diagnosis of HD should be confirmed in an affected member of the family to be certain that the disease in the family is indeed HD. Excluding HD cannot rule out a different dominantly inherited neurodegenerative disease in the family for which the patient likely retains a risk of development. Since HD is a delayed-onset disease, as the asymptomatic at-risk patient ages, the risk of testing positive with an expanded CAG repeat decreases.[240] Thus should the patient elect not to have predictive testing, the genetic counselor can provide information regarding the probability that an HD mutation exists, which based on the individual's age, may provide some comfort to the patient.

Prenatal testing for HD is another complicated issue associated with this disease and may not be provided in all laboratories that perform routine HD testing. If a molecular genetics laboratory chooses not to provide prenatal testing (e.g., because of the possibility of termination of a pregnancy for a late-onset disorder or because it constitutes presymptomatic testing of the child should the parents choose not to terminate), it is the responsibility of the laboratory to identify an alternative source of testing to which the patient can be referred. Before the cloning of the HD gene, prenatal testing was performed using linkage studies, and the likelihood that the child would develop HD was "excluded" if the child had inherited an HD haplotype from an unaffected grandparent.[379,586] The concept of exclusion testing was difficult to understand, however, and not all families were heterozygous for the DNA markers thereby making the test inconclusive. In some instances, the status of the parent at risk for developing the disease was also revealed. Moreover, testing could in theory lead to abortion of 50% of fetuses who had not inherited HD but rather had inherited the normal HD allele from the affected grandparent. To eliminate some of the controversy of prenatal testing for HD, preimplantation genetic testing (PGT) can be performed. In PGT in vitro fertilization is used to produce embryos that then have a biopsy performed for analysis of their HD genes. Once PCR has been used to determine the HD CAG-repeat numbers, only embryos with normal HD alleles are implanted. This methodology, combining direct mutation analysis and PGT, eliminates the necessity for prenatal testing to determine the HD status of the fetus since the HD alleles of the fetus are known to be normal, and the need for termination of a pregnancy is eradicated. Further, this can also be performed without disclosing the HD status of the asymptomatic, yet at-risk parent. However, this approach of nondisclosure PGT can pose ethical problems to the testing personnel.[78] In some testing centers, PGT may be performed by direct mutation analysis in families for which the at-risk parent is knowledgeable regarding his or her carrier status, and embryos with only normal HD alleles are implanted. Alternatively, in families in which the parent is unaware of his or her HD status, PGT can be performed using exclusion testing whereby only embryos who have not inherited an affected grandparent allele are implanted, and the size of the HD CAG-repeat number is not determined.[78,520-521]

X-Linked Diseases

In X-linked diseases, the mutant allele resides on the X chromosome. In X-linked recessive diseases, females are carriers of the disease with one normal and one mutant allele but typically are not affected. Males receiving the mutant allele from their mothers and having only one X chromosome have no normal allele and thus are affected. All daughters of affected males are carriers of a mutant allele. Carrier females have a 25% chance of transmitting their normal allele to a son, a 25% chance of having an affected son, a 25% chance of having a daughter who carries the mutant allele, and a 25% chance of having a daughter who receives her normal allele. In the absence of a family history, an affected male can have a mutant allele that rose de novo as a new mutation during the formation of the egg. Roughly one third of all cases of X-linked disorders represent new mutations indicating that the mother is not a carrier of a mutant allele and not at risk for subsequent affected children. In pedigrees associated with X-linked recessive conditions, typically only males are observed, and male-to-male transmission of the disease is not seen. In less frequent X-linked dominant diseases, one copy of the mutant allele is sufficient to cause disease despite the presence of a normal allele. Further, in males with only a mutant allele, these diseases are often lethal.

Hemophilia A

Hemophilia A is an X-linked recessive bleeding disorder caused by a deficiency of coagulation factor VIII (FVIII) and affects approximately 1 in 10,000 males worldwide. The disease is characterized by prolonged bleeding after injuries or surgery, renewed bleeding after the initial bleeding has ceased, and in severe cases, spontaneous bleeding into the joints. The severity of the disease is determined by the amount of FVIII coagulant activity present in the plasma; mild, moderate, and severe disease have corresponding FVIII activity levels of 5% to 30%, 1% to 5%, and <1% of control,

respectively. In the patient with severe or moderate hemophilia A disease, the activated partial thromboplastin time (aPTT) will be prolonged while all other routine coagulation test results are normal. In patients with mild hemophilia A disease, however, aPTT is often normal. The age of diagnosis is typically earlier in cases with severe disease and a family history.[106] Although most patients with severe disease are diagnosed in the first year of life, patients with mild disease may not be diagnosed until several years later. Although hemophilia A is an X-linked disease and typically presents in males, females with the disease have been reported. Carrier females can present with severe disease caused by skewed X-chromosome inactivation in which the X chromosome with the mutant *FVIII* gene is not inactivated, or alternatively the female may have a mutant *FVIII* gene on each of her X chromosomes.[391,517,590,633]

The *FVIII* gene is positioned on Xq28 (long arm of the X chromosome band 28) and was cloned in 1984.[205,409] The gene spans more than 186,000 base pairs and includes 26 exons.[21] A plethora of nucleotide substitutions, gene deletions, insertions, and rearrangements throughout the *FVIII* gene have been reported in patients with hemophilia. The variability accounts for much of the clinical heterogeneity that is observed with this disease.[393,583] Interestingly, although routine screening of the coding, splice junctions, promoter region, and polyadenylation site of the gene could detect the mutation in the majority of patients with mild to moderate disease, the disease-causing mutation in about half of the patients with severe disease remained elusive for several years.[258]

In 1993 a common inversion mutation was identified in approximately 45% of patients with severe disease.[319,414] The inversion mutation arose from genetic recombination between a small intronless gene within intron 22, gene A, and one of two additional copies of the gene A located approximately 500 kb upstream from the *FVIII* gene. The mechanism for the inversion involves flipping of the tip of the X chromosome allowing pairing between homologous sequences and genetic recombination between one of the upstream copies of gene A and the copy of gene A within intron 22. Consequently the *FVIII* gene is divided into two parts, with exons 1 to 22 widely separated and in an opposite orientation and thus inverted from exons 23 to 26. The majority (>75%) of inversion mutations involve the distal copy of gene A upstream from the *FVIII* gene as compared with the adjacent proximal copy of gene A.[319] Rossiter et al showed that this genetic recombination between homologous intragenic and extragenic copies of gene A occurred as a new mutation predominantly during male meiosis with a male-to-female ratio of 302:1.[492] Since during male meiosis Xq is unpaired with a homologue, it is able to flip on itself for an intrachromosomal recombination event. The role of this mutation as a primary cause of severe hemophilia A disease was subsequently confirmed by the analysis of DNA from patients with hemophilia from around the world.[22] Additionally, this mutation has been identified in the Chapel Hill dog colony with hemophilia A disease and presumably arose from the same mechanism of genetic recombination between homologous sequences.[344] Although the causative mutation in the majority of patients can be identified through a combination of various screening techniques, in 1% to 2% of patients the causative *FVIII* gene mutation is not identified.[305] These may represent patients with mutations in upstream regulatory sequences or at other gene loci whose proteins interact with the FVIII molecule.

FVIII is synthesized as a single polypeptide chain of 2351 amino acid residues and an approximate weight of 280 kD.[599] The encoded FVIII protein is predominantly produced in the liver, circulates in the plasma, and is stabilized through noncovalent binding to the complex multimeric glycoprotein von Willebrand's factor (vWF). In the intrinsic coagulation pathway, proteolytic activation of FVIII by small amounts of thrombin frees it from vWf, where it then participates as a cofactor with activated factor IX to catalyze the conversion of factor X to factor Xa.[168] Factor Xa hydrolyzes and activates prothrombin to thrombin. As the concentration of thrombin increases, FVIIIa is ultimately cleaved by thrombin and inactivated. This dual action of thrombin on FVIII regulates the formation of the FVIIIa, IXa, and X complex and thus regulates the clotting cascade. A deficiency of coagulation FVIII then leads to uncontrolled bleeding. The treatment for bleeding episodes is intravenous infusions of FVIII concentrate as quickly as possible to prevent pain, disability, and chronic joint disease. Children with severe hemophilia can be given prophylactic infusions of FVIII concentrate to maintain their clotting activity above 1% and decrease the number of spontaneous bleeding episodes.[349] As a result, clotting factor consumption has increased dramatically over the years and is quite costly but has significantly decreased hemophilic arthropathy.[178] However, management of 15% to 33% of severe and moderately affected patients is complicated by antibody formation to exogenous FVIII caused by repeated infusions. The antibodies can rapidly neutralize infused FVIII. Interestingly the antibodies produced by many patients have hydrolytic activity toward FVIII.[318] Management of the disease was further complicated in hemophilia patients who had contracted human immunodeficiency virus (HIV) and/or hepatitis C virus (HCV) from contaminated plasma-derived FVIII concentrates in the early 1980s. Fortunately, with mandatory and improved screening for these and other viruses, these products are considerably safer, but fears are not completely alleviated.[26] For these reasons, there is great interest in gene therapy for the treatment of hemophilia; several clinical trials have been completed, and others are underway.[387,628] Thus far low levels of FVIII expression have been observed in all trials and have been associated with clinical improvement.

In the mid1980s, after the discovery of the *FVIII* gene and before our current technology of rapid DNA sequencing, DNA testing for hemophilia A primarily involved the use of linkage studies and restriction fragment length polymor-

phisms to determine the carrier status of at-risk females in the family and to perform prenatal testing.[23,634] Although accurate, these studies could be complicated by (1) the large number of family members required for participation in the analysis, (2) a limited number of alleles for each marker (limiting the chance that key members of the family would be informative [i.e., heterozygous] for a given marker), and (3) genetic recombination between the informative marker and the *FVIII* gene mutation, which could affect the accuracy of the results. Moreover, in the absence of a family history, the carrier status of the mother of a sporadic case was uncertain (though as many as two thirds of these mothers might be carriers). PCR and the analysis of polymorphic microsatellite repeats within the *FVIII* gene increased the number of families in which linkage studies could be performed and significantly improved turnaround times.[320]

The most significant improvement in DNA testing was the identification of the inversion mutation in families with severe disease and the ability to offer direct mutation analysis as opposed to linkage studies.[290,610] As a result, the carrier status of the mother of a sporadic case with a detectable inversion mutation could now be determined with certainty, and her risk for another affected son could be precisely predicted to be 25% (Figure 40-6). In addition, prenatal and carrier testing results would be completely informative and accurate and would not be subjected to inaccuracy caused by the possibility of genetic recombination. Subsequently a PCR assay for the detection of the inversion mutation was developed. It eliminated the necessity for labor-intensive and expensive Southern blot analysis and significantly improved turnaround times.[340-341] For clinical samples, if the patient has a negative test result for a common inversion mutation, DNA sequence analysis of the *FVIII* gene is typically performed, and the turnaround time is about 4 to 8 weeks. Once the mutation segregating in the family has been identified, direct mutation testing for prenatal studies or the carrier status for other at-risk females in the family is available with a usual turnaround time of 2 weeks.[196]

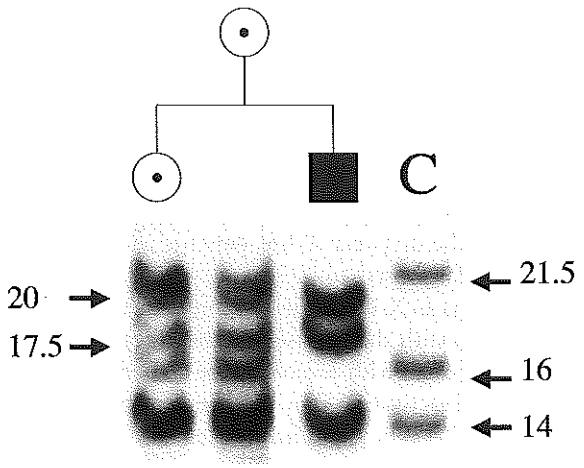

Figure 40-6 Southern blot analysis for the detection of a common inversion mutation present in the DNA of about 50% of patients with severe hemophilia A disease. Patient DNA is digested with restriction endonuclease *BclI*, blotted to a nylon membrane, and hybridized with a ^{32}P-labeled probe corresponding to sequences in intron 22 of the factor VIII gene. Autoradiography was at −70 °C for 24 hours. Normal control DNA (*lane C*) yields bands 21.5 kb, 16 kb, and 14 kb in length. The pattern observed for the affected male *(shaded box)* in this family yields an altered banding pattern with bands of 20 kb, 17.5 kb, and 14 kb. Bands of these sizes confirm the presence of an inversion mutation resulting from homologous recombination between a copy of gene A within intron 22 of the factor VIII gene and the distal copy of gene A 5′ to the factor VIII gene. DNA analysis of the patient's mother and sister indicates that they are carriers of the inversion mutation with bands at 21.5 kb, 16 kb, and 14 kb generated from their wild-type allele and bands at 20 kb, 17.5 kb, and 14 kb generated from their mutant allele. Identification of the inversion mutation in this family will facilitate accurate carrier screening in other at-risk females in this family.

Duchenne's Muscular Dystrophy

Duchenne's muscular dystrophy (DMD) is an X-linked recessive disorder characterized by progressive skeletal muscle wasting. The incidence of DMD is about 1 in 3500 male births, making it the most common severe neuromuscular disease in man. The onset of DMD is typically before 3 years of age with gait difficulty, progressive myopathic weakness with pseudohypertrophy of calves, and grossly elevated serum creatine kinase (CK) as a result of degenerating fibers. Electromyography and muscle biopsy are used to confirm the diagnosis. In Wales, newborn screening of plasma creatine kinase has been used to identify affected males before the onset of clinical signs and to prevent delay in the diagnosis.[440] In this scenario, after informed parental consent, if the diagnosis is made at this time, immediate pediatric and genetic services can be offered to the families.

Most DMD patients are wheelchair bound between 10 and 15 years of age. Continual degeneration and regeneration of muscle eventually lead to the replacement of muscle tissue by adipose and connective tissue, causing progressive disease; death usually occurs before the age of 30 from respiratory or cardiac failure. Carrier females can be asymptomatic or have varying degrees of clinical symptoms depending on the degree of inactivation of the X chromosome harboring the mutant DMD gene in the various tissues where the DMD protein is expressed.[266] Females with severe disease most often result from a carrier female with skewed lyonization or an X-autosome translocation involving the *DMD* gene.*

Cytogenetic abnormalities in DMD patients and DNA linkage studies localized the DMD locus to Xp21 (the short arm of the X chromosome band 21).† Mixing DNA enhanced for X-linked genes from a 49,XXXXY cell line with DNA

*References 77, 217, 478, 606, 645, 647.
†References 31, 131, 184, 217, 409, 606, 647.

from a patient with DMD and a cytogenetic deletion in Xp21, Kunkel et al cleverly used subtraction hybridization to clone the DNA corresponding to the patient's deletion.[316] The deleted region was cloned because during the hybridization, the X-linked sequences from the cell line had no complementary sequences with which to anneal in the patient's DNA and thus were available for cloning. Subsequently, this cloned DNA was found to detect deletions in DMD patients.[315,385] A complete 14 kb cDNA transcript was eventually cloned from fetal skeletal muscle and was used to detect deletion mutations in 53 of 104 patients.[307]

The *DMD* gene is the largest gene in the human genome known to date, spans 2.2 megabases (Mb), contains 79 exons, and has multiple promoter regions.[138,261] The protein product, dystrophin with 3685 amino acids, has a molecular weight of 427 kD and represents approximately 0.002% of total striated muscle protein. Dystrophin is a cytoskeletal protein associated with a protein complex, dystrophin-associated protein complex (DAPC), which in skeletal muscle plays a structural role connecting the actin cytoskeleton to the extracellular matrix, stabilizing the sarcolemma during repeated cycles of contraction and relaxation, and transmitting force generated in the muscle sarcomeres to the extracellular matrix.[154,571] Without dystrophin, an integral component of DAPC, sarcolemmal integrity is compromised. As a result, there is an influx of extracellular calcium triggering calcium-activated proteases and fiber necrosis.[547] Other roles for DAPC have also been proposed, indicating that several mechanisms may be involved in the DMD phenotype.[229,467,470,506] Gene expression studies of diseased and normal muscle have revealed the overexpression of genes involved in muscle structure and regeneration processes.[242,425] Further characterization of the genetic profiles between normal and diseased muscle may help elucidate the molecular mechanisms underlying the dystrophic changes and muscle hypertrophy seen in DMD patients. Although not yet reality, technological advances in many areas of science and medicine suggest that gene therapy for DMD lies in the not so distant future.[104,485]

Because of the tremendous size (2.2 Mb), complexity (8 promoters), and diversity of mutations within the *DMD* gene, DNA testing for DMD presents a challenge for clinical laboratories.[331] Although DNA testing is often not required for diagnosis, because findings on immunohistochemical studies on a biopsy of muscle tissue are considered as diagnostic, identification of the mutation causing the disease in a family is required for carrier detection of at-risk females and for prenatal testing. Intragenic deletions, most often encompassing multiple exons, represent about 60% to 65% of all mutations, affect the translational reading frame of the protein, and lead to a truncated and nonfunctional protein. Duplications of gene sequences are observed in about 5% of patients. Both deletions and duplications can be rapidly detected by use of a combination of multiplex PCR reactions. Electrophoretic gels of the amplified DNA will show the loss of a band or bands or an increased intensity of one or more bands.[46,105] Duplications in affected males and carrier females and deletions in carrier females can be more difficult to observe but can be detected using an endogenous internal standard.[273,464] Detection of the remaining 30% of mutations is tedious, labor intensive, and often beyond the scope of most clinical laboratories. Many of these mutations are within noncoding parts of the gene and are private (i.e., unique to a single patient).[465] Such *DMD* gene mutations have been detected by use of one of a variety of reported techniques, including denaturing gradient gel electrophoresis, protein truncation test, heteroduplex analysis, single-strand confirmation polymorphism, and DNA sequencing.[146,181,192,373,465]

Becker muscular dystrophy (BMD), a milder and less common form of muscular dystrophy with an estimated incidence of 1 in 18,500 births, is an allelic variation of DMD caused by different mutations within the *DMD* gene.[45,94,118,262,643] About 55% of BMD patients have deletions within the dystrophin locus, with those having deletions around the distal rod domain of dystrophin (exons 45 to 60) showing a more classic BMD phenotype and in some cases even remaining free of symptoms until their 50s. However, BMD patients with deletions involving the amino-terminal domain of dystrophin (exons 1 to 9) have a more severe phenotype with an earlier age of onset and a more rapid progression of disease. Patients with X-linked dilated cardiomyopathy (DCM) have also been shown to have mutations at the dystrophin locus.[175,378,396,435] The pattern of mutations in dystrophin causing DCM is less well characterized, with alterations reported in various regions including the promoter region, exon:intron junction splice sites, and various exons throughout the gene.

For DMD or BMD families in which no deletion or duplication is detected, carrier and prenatal testing can be offered by clinical laboratories using DNA linkage studies. However, since the intragenic recombination frequency for this gene is estimated to be about 12%, these studies require the use of both multiple intragenic and 5′ and 3′ flanking markers for an accurate carrier or prenatal result.[3] Particularly difficult are sporadic cases of DMD or BMD in which no other family member with DMD or BMD is known and no mutation in the affected individual is detected. Generally, one third of sporadic cases are thought to represent a new mutation in the mother's gamete from which that individual was derived. Thus neither the mother nor female siblings would be carriers, and the risk to the mother for a second affected son would be considered minimal.

In 1987 Bakker et al first described the phenomenon of germline mosaicism in which no *DMD* gene mutation is present in lymphocyte DNA, but *DMD* gene mutations are present in the germline tissue.[32] Presumably these mutations occur during mitosis in germline proliferation and explain the report of multiple affected children of women whose lymphocyte DNA contains no *DMD* mutations.

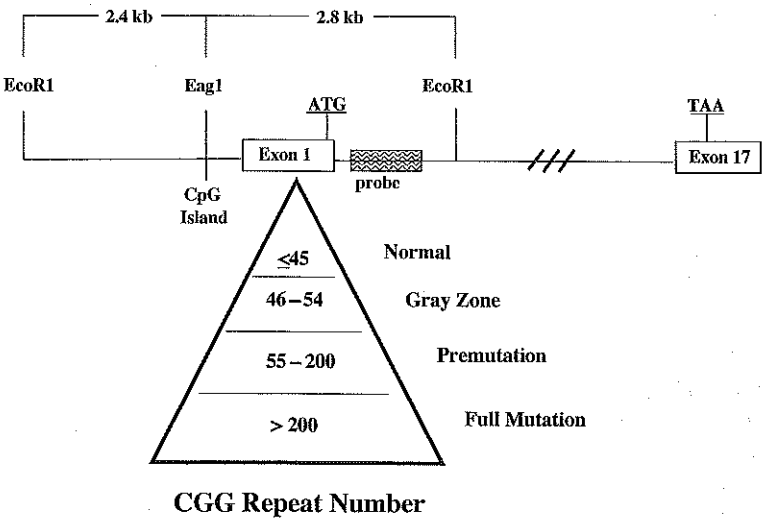
In mutation-negative families, carrier assessment involves measurement of serum CK activity and linkage studies.[276]

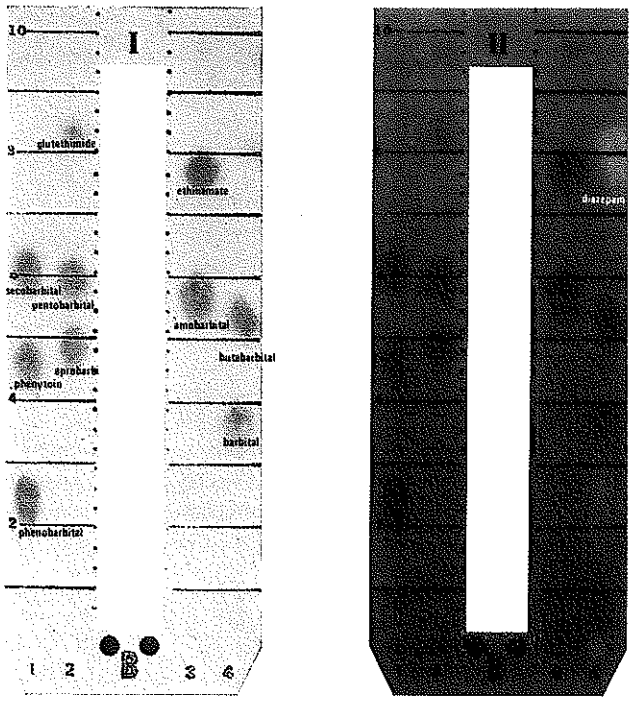
Carrier assignment, however, is not perfected. Linkage studies are complex, require participation of multiple family members, and are confounded by inaccuracy caused by meiotic recombination or germline mosaicism. Serum CK is, by definition, above the reference interval (defined as the 95th percentile of a healthy reference group of age-matched women) in ~1 of 20 noncarrier women. Moreover, serum CK decreases in DMD carrier women as they age. Thus for DMD and/or BMD families, identification of the mutation in the family best enables rapid and accurate direct mutation analysis for carrier and prenatal testing in that family.

Fragile X Syndrome

Fragile X syndrome is one of the most commonly inherited forms of mental retardation, with an estimated incidence of 1 in 3500 males and 1 in 9000 females.[123] The name of the condition reflects the cytogenetic abnormality of a breakpoint or fragile site in the X chromosome. The clinical syndrome was first described by Martin and Bell in 1943 in a family with sex-linked mental retardation in both males and females who had no dysmorphic features.[360] The disease was later redefined by Lubs, who noted the presence of a marker X chromosome in the leukocytes of some mentally retarded males following incubation of cells in cell culture media depleted of folate and thymidine; the marker segregated with mental retardation in the family.[345] The chromosomal locus for this fragile site would later be localized to Xq27.3 (the long arm of the X chromosome band 27.3).[241,409] Common clinical features associated with fragile X syndrome are mental retardation, delayed motor and speech development, macroorchidism, long face, prominent forehead and jaw, large ears, flat feet, and abnormal behavioral characteristics that include hyperactivity, hand flapping, temper tantrums, persevering speech patterns, poor eye contact, and occasionally autism.[136] These features are often less frequent and milder in affected females than in affected males because of random X inactivation of their abnormal fragile X gene and expression of their normal gene in half of their tissue.

As a sex-linked disease, fragile X syndrome has a complicated inheritance pattern. Affected females are heterozygous for the mutation, and unaffected males can transmit the mutation through the family. For this reason, Sherman et al proposed that fragile X syndrome was an X-linked dominant disorder with reduced penetrance (79% for males and 35% for females), but the penetrance of the disease appeared to increase in subsequent generations within a family.[524,526] The mechanism of this "Sherman paradox" was resolved when the gene causing fragile X syndrome, *FMR1* (Fragile X Mental Retardation) was cloned in 1991.[47,310,430,607,646] *FMR1* was the first gene discovered to cause disease through an expansion of an unstable trinucleotide repeat sequence. The unstable CGG repeat is located in the 5′-untranslated region of the *FMR1* gene in exon 1. The gene spans 38 kb, contains 17 exons, and encodes a 4.4 kb transcript.[156] Alleles contain blocks of CGG repeats usually 7 to 13 repeats in length, which can be interspersed with single AGG repeats.[317,539] Allelic diversity results from the variable number and lengths of these CGG-repeat blocks. There are no distinct boundaries separating the repeat number categories, however. Normal alleles have 5 to 45 repeats; gray zone alleles have 46 to 54; premutation alleles have 55 to 200; and full mutation expansion alleles contain >200 repeats[354] (Figure 40-7). Individuals with a normal number of CGG repeats do not have fragile X syndrome nor are they at risk of having an affected child. Individuals with 46 to 54 repeats represent alleles in the upper range of normal or a smaller than average premutation allele. These individuals do not have fragile X syndrome, yet may have a slightly increased risk of repeat instability and expansion to a full mutation in their offspring in some families. Premutation alleles are unstable and can expand to a larger allele in the premutation range when





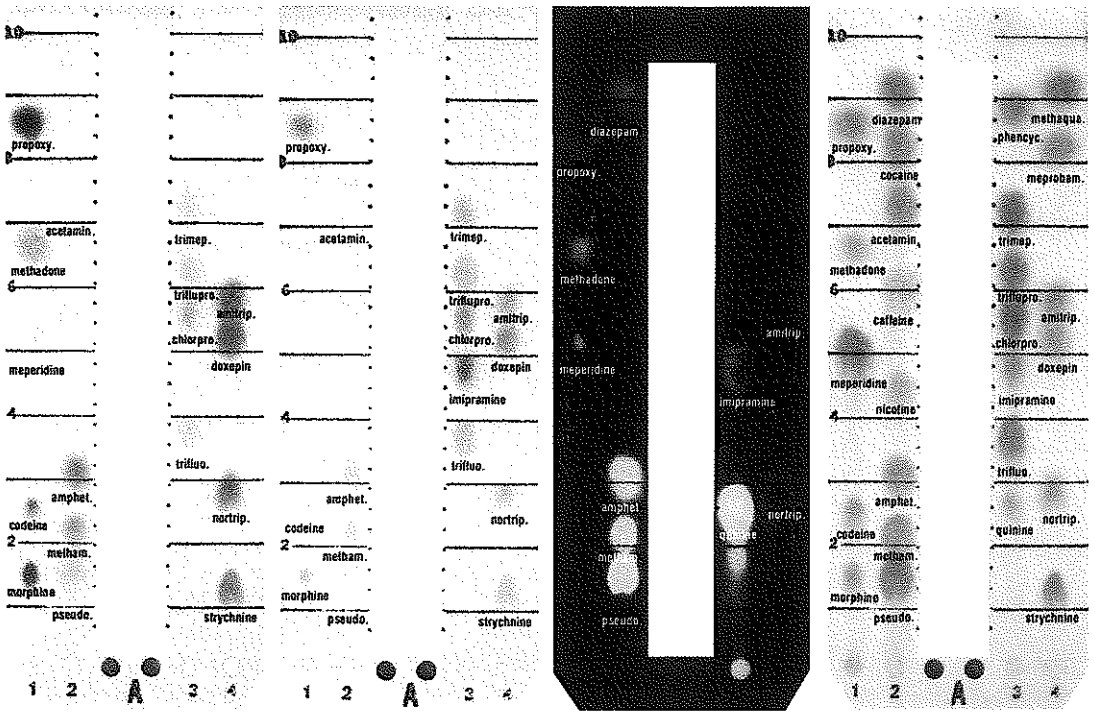


Figure 40-7 Schematic representation of the CGG repeat in exon 1 of *FMR1* and associated alleles. A CGG-repeat number less than or equal to 45 is normal. A CGG-repeat number of 46 to 54 is in the gray zone and has been reported to expand to a full mutation in some families. A CGG-repeat number of 55 to 200 is considered a premutation allele and is prone to expansion to a full mutation during female meiosis. A CGG-repeat number in excess of 200 is considered a full mutation and is diagnostic of fragile X syndrome.

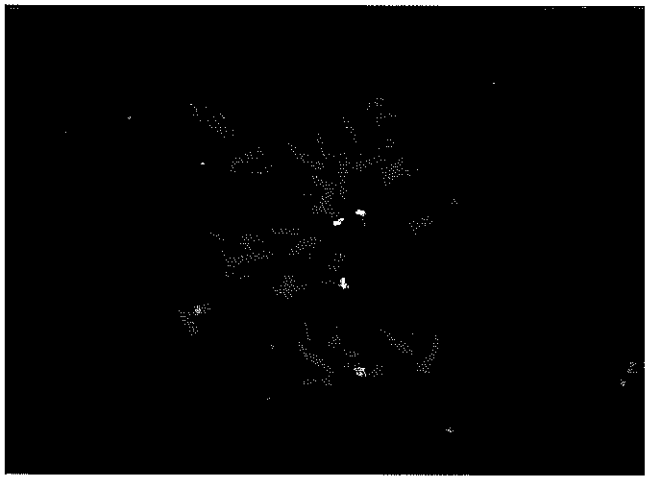
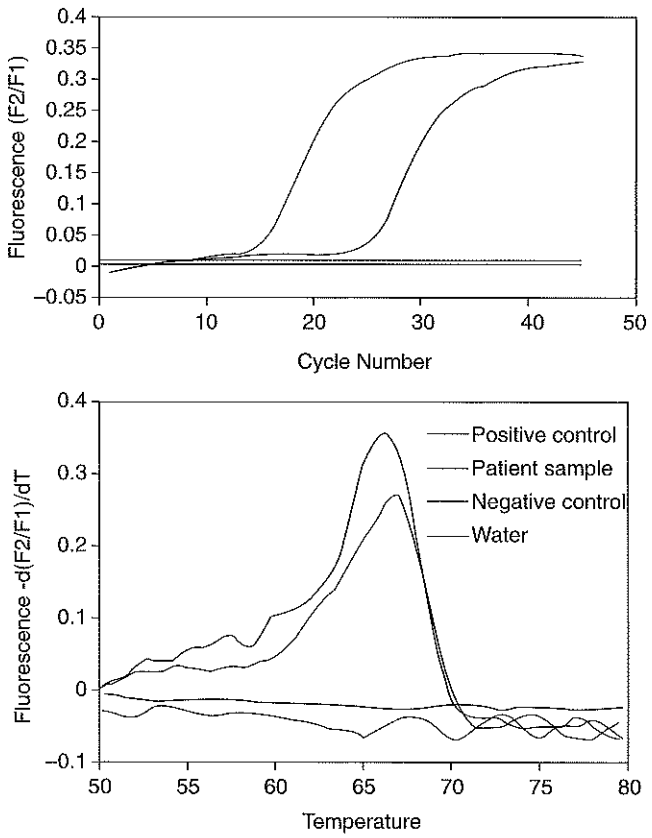
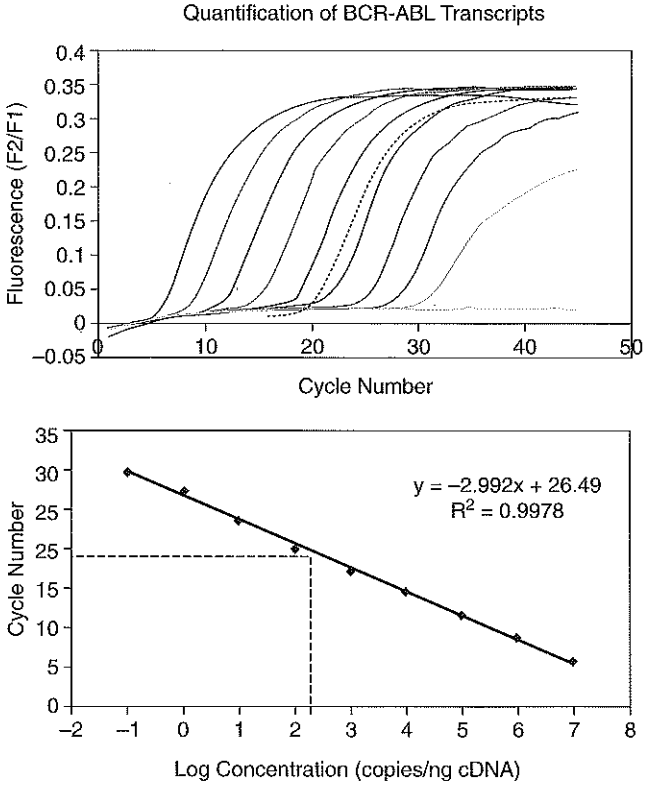
TOXI-LAB® B WORKSHEET



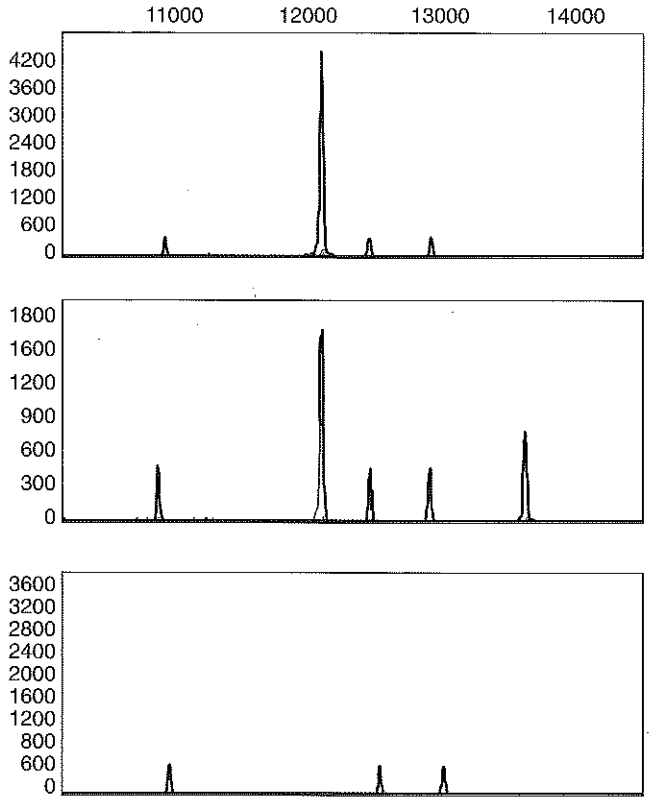
TOXI-LAB® A WORKSHEET



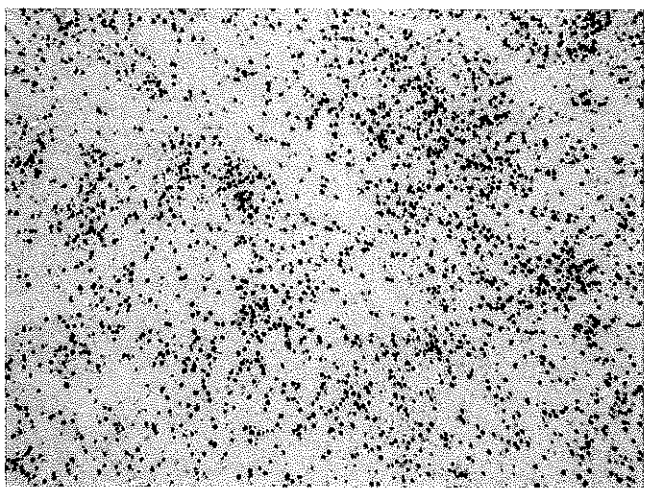
Some variation in the color and position of the drug spots is normal.



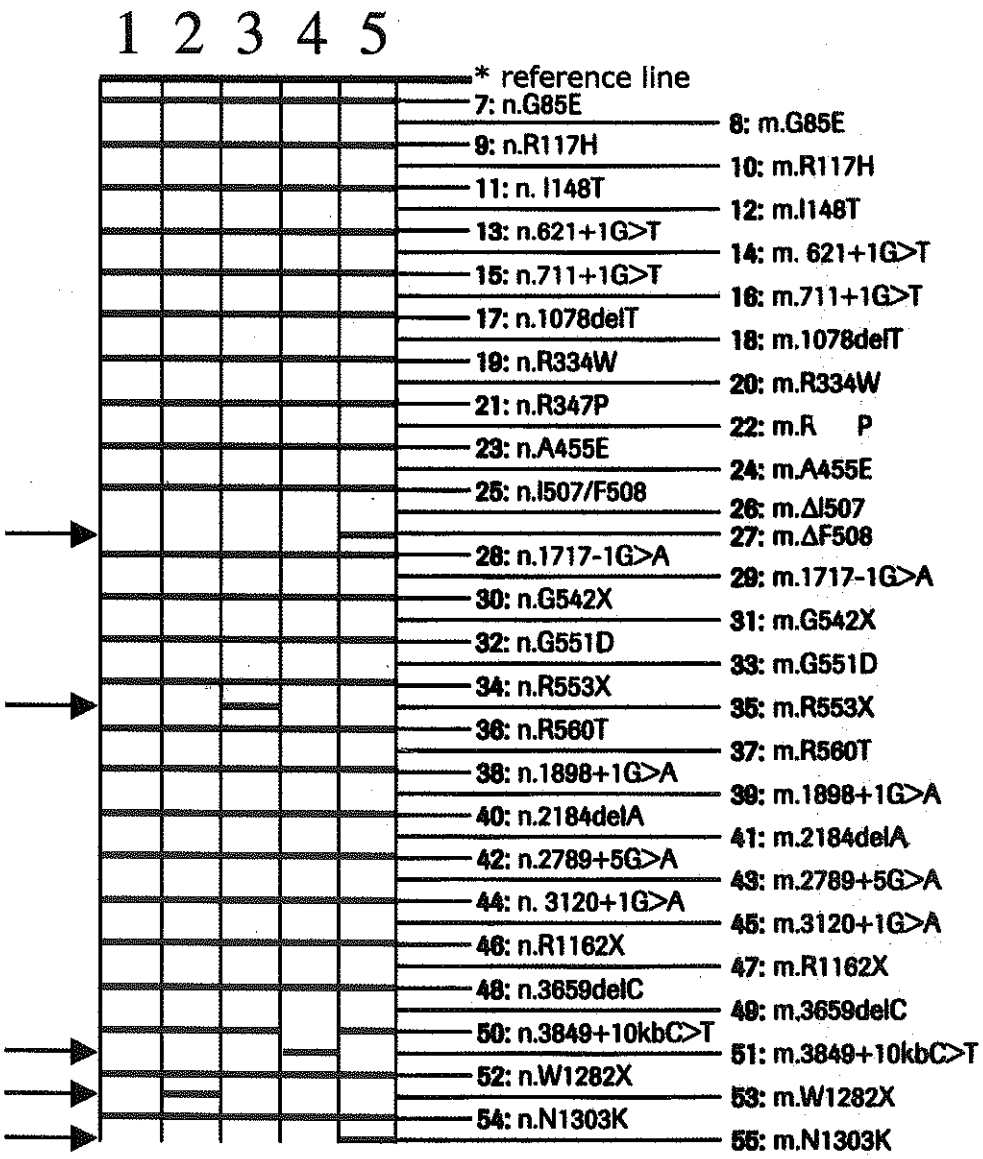
Color Plate 1 Examples of TLC plates used in drug screening: basic drugs (B Worksheet) and acidic, neutral drugs (A Worksheet). (See Figure 34-1.) *(Reproduced with permission of Toxi-Lab, Inc., Irvine, Calif.)*



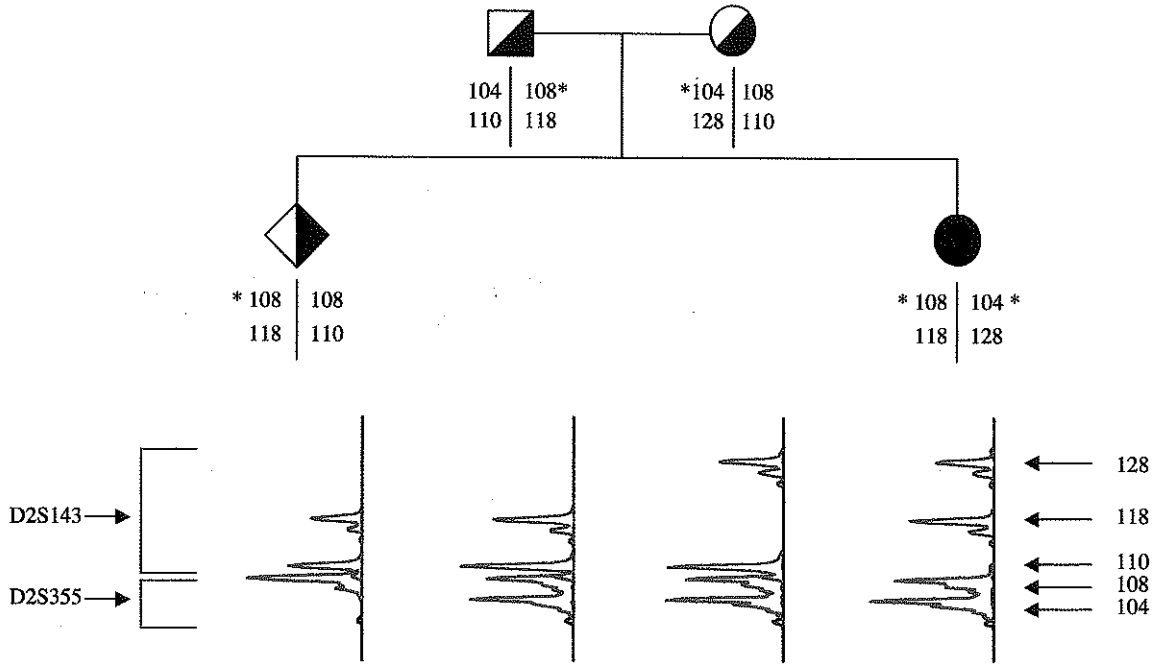
Color Plate 2 Fluorescence in situ hybridization for the t(14;18) anomaly on metaphase spreads of a case of follicular lymphoma. The immunoglobulin heavy chain sequences on 14q32 *(red)* when juxtaposed to the *bcl-2* sequences on 18q21 *(green)* yield a yellow fusion signal indicative of the presence of the t(14;18). (See Figure 39-9.)



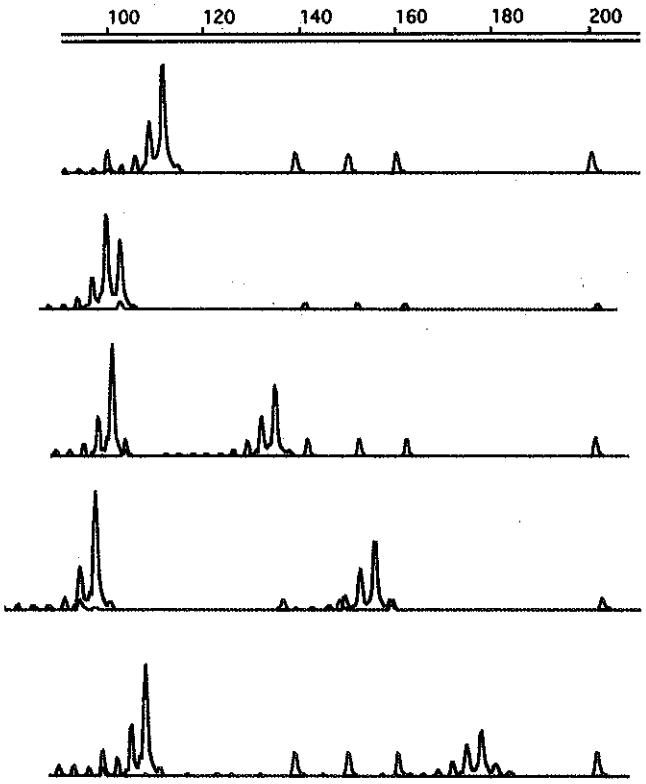
Color Plate 3 Real-time PCR detection of *AML1/ETO* fusion transcript. Real-time PCR detection was performed using a sequence-specific hybridization probe format with oligonucleotide probes labeled with fluorescein as the donor fluorophore and LCRed640 as the acceptor. Postamplification melting analysis was performed to provide confirmation of amplicon identity through the probe melting temperature. Panel A shows the fluorescence (F) versus cycle number (C) the LightCycler™ (Roche Diagnostics). The characteristic three-phase profiles of amplification curves are recognizable (i.e., initial lag, exponential or log/linear, and the final plateau phase). The red curve represents the positive amplification signal for the t(8;21) in the Kasumi cell line positive control. The blue curve represents the patient sample also showing the presence of the *AML1/ETO* fusion. The green line represents a negative control (placental cDNA), and the black line is the no-template (H_2O) control. Panel B shows the derivative melting curves with positive melting peaks at ~65°C in both the Kasumi cell line positive control and the patient sample. Both the negative and water controls show flat lines indicating the absence of the t(8;21) *AML1/ETO* product. (See Figure 39-12.)



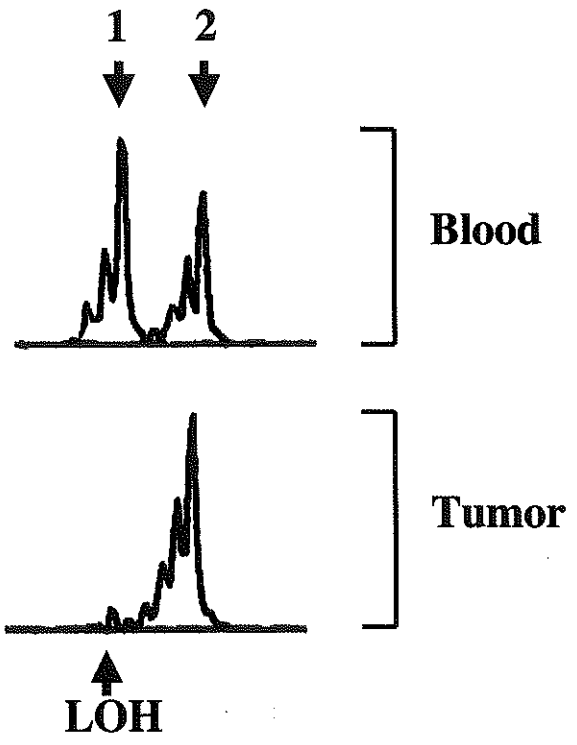
Color Plate 4 Real-time quantitative PCR of *BCR-ABL* transcripts. Serial log dilutions of the plasmids containing the *BCR-ABL* transcripts. Real-time PCR provides a remarkable dynamic range of quantification (10^9 to 10^0 template copies) in this example. The upper panel shows the amplification curves obtained using the *BCR-ABL* containing plasmids and an unknown patient sample depicted as a dotted line. Note the regular ~3.3-cycle interval between log dilutions. The lower panel shows a standard curve (linear regression of cycle number versus log template concentration). As indicated by the dotted line in the lower panel, the cycle threshold (onset of the log-linear phase of the amplification curve) can be used to quantitate the copy number of the target in the tested sample. (See Figure 39-15.)



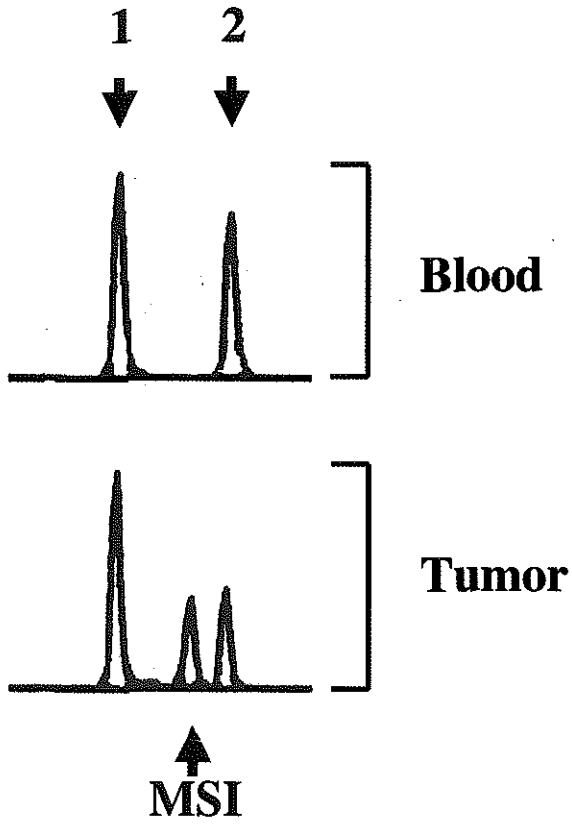
Color Plate 5 Detection of internal tandem duplications of the *FLT3* gene by PCR and capillary gel electrophoresis of PCR products. Capillary electropherograms show clear resolution of PCR products. The x-axis represents the sizes of PCR products and the y-axis shows the fluorescence intensity, which correlates with the abundance of the PCR product. The upper panel shows a wild type of pattern *(blue peak)*. The middle panel shows an additional peak of greater size than the wild-type peak *(blue peak on the left)*. The blue peak on the right represents a *FLT3* internal tandem duplication. The lower panel shows the size markers *(red peaks)* also present in the upper and middle panels. (See Figure 39-16.)



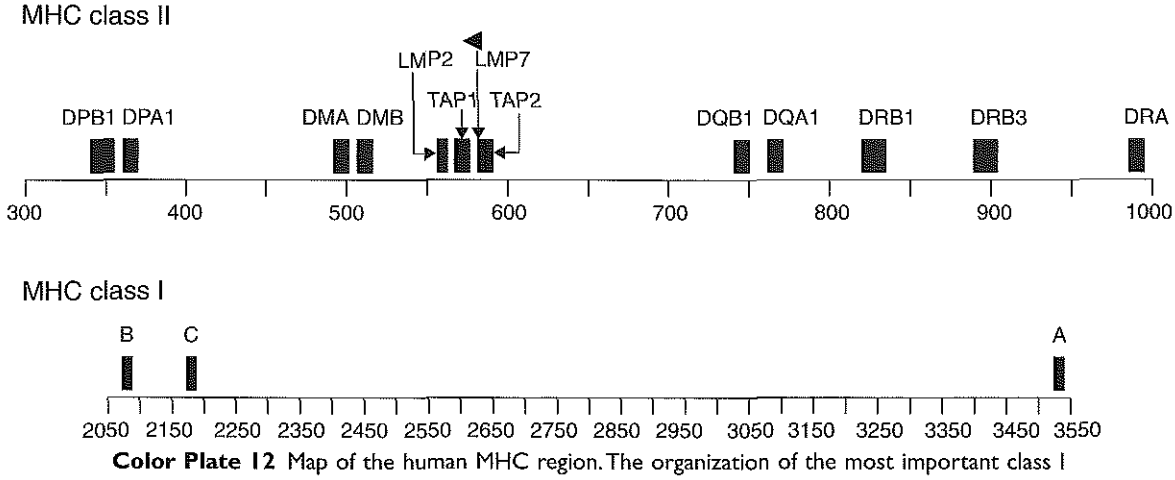
Color Plate 6 In situ hybridization (ISH) for the Epstein-Barr virus (EBV). ISH hybridization for EBV shows numerous positive signals *(dark-blue spots)* for EBV using the EBER-1 probe. The tissue sample was obtained from a solid-organ transplant patient who developed widespread nodal and extranodal masses. The positive reaction for EBV in this assay supports a diagnosis of posttransplant lymphoproliferative disease. (See Figure 39-17.)



Color Plate 7 CF mutation-detection assay CF Gold 1.0 developed by Roche Diagnostics Corp. Thirty to 45 ng of patient DNA is amplified in a multiplex amplification reaction. Amplicons are denatured and hybridized to membrane-bound oligonucleotide probes specific for 25 normal (n) and corresponding mutant (m) alleles. Lane 1 represents the pattern obtained from patient DNA in which none of the 25 common mutations is present; bands detected correspond only to normal alleles. Lane 2 represents the pattern obtained from patient DNA in which mutation W1282X is present in one allele, since bands corresponding to both nW1282X and mW1282X are present. In lane 3, mutation R553X is present in one allele since bands corresponding to mR553X and nR553X are present. Lanes 2 and 3 could represent CF carriers or could represent DNA from patients with CF for whom only one of their two mutations is identified. In the latter case, the second disease-causing mutation must be a mutation other than one of the 25 represented in this panel. Conversely, lane 4 represents patient DNA in which two copies of mutation 3849 + 10kbC>T are detected. Note that no band corresponding to n3849 + 10kbC>T is present. Lane 5 represents DNA from a CF patient who is a compound heterozygote with mutation delta F508 present on one allele and mutation N1303K present on the second mutant allele. Detection of 5, 7, or 9 T polymorphism in intron 8 has not been determined in these patients but can be performed by this assay. The strip contains oligonucleotide probes for the determination of this polymorphism in patient DNA above the reference line. However, before testing, this part of the strip is removed and is only performed as a reflex test if mutation R117H is detected. (See Figure 40-1.)



Color Plate 8 Electropherograms illustrating prenatal DNA-linkage studies on a family with CPSI deficiency D2S355 and D2S143 represent dinucleotide markers 4 centimorgans 5′ (D2S355) and 3 centimorgans 3′ (D2S143) to the *CPSI* gene, respectively. DNA samples from the affected child, parents, and fetus are amplified by PCR using oligonucleotide primer pairs specific for each marker, with one primer of each pair labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel on an ABI 377 DNA sequencer and analyzed using GeneScan software 3.1b3. The maternal haplotype donated to the affected child is 104,128, indicating that her 108,110 allele is not linked to an abnormal *CPSI* gene. The paternal allele donated to the affected child is 108,118, indicating that his 104,110 allele is in repulsion with CPSID. The maternal allele donated to the fetus is 108,110. This allele is not linked to an abnormal *CPSI* gene. The paternal allele donated to the fetus is 108,118. This allele is linked to an abnormal *CPSI* gene. These results indicate that the fetus is a carrier of CPSID but is not affected. (See Figure 40-3.)



Color Plate 9 Electropherograms representing various patterns observed in patients referred for HD testing. The polyglutamine-encoding CAG repeat in exon 1 is amplified by PCR using flanking oligonucleotide primers, one of which is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel on an ABI 377 DNA sequencer and analyzed using GeneScan software 3.1 b3. Amplicons 100 bp in length contain 18 CAG repeats and flanking DNA. Patient one *(row 1)* has amplicons 112 bp in length and has 22 CAG repeats on both HD alleles. Patient two *(row 2)* has 97 bp and 100 bp amplicons, corresponding to CAG repeats of 17 and 18. The diagnosis of HD can be ruled out in these two patients. Patient three *(row 3)* has 97 bp and 133 bp amplicons corresponding to CAG repeats of 17 and 29. The results would not support a diagnosis of HD. However, a CAG repeat of 29 is mutable and can undergo meiotic expansion to an HD allele. Patient four *(row 4)* has CAG repeats of 19 and 38 as depicted by amplicons 103 bp and 160 bp in length. In the symptomatic patient, these results would support the diagnosis of HD. However, in the presymptomatic patient, the phenotype of this HD allele with reduced penetrance cannot be predicted with certainty. Patient five *(row 5)* has CAG repeats of 21 and 44 since amplicons 109 bp and 178 bp in length were detected. These results would confirm the diagnosis of HD. Genetic counseling regarding the implications of the DNA findings in patients three, four, and five is indicated. (See Figure 40-5.)

Color Plate 10 Electropherograms illustrating LOH in tumor DNA. Patient DNA is extracted from the peripheral blood and tumor tissue and amplified by PCR using an oligonucleotide primer pair specific for a polymorphic, microsatellite repeat locus contained within the chromosomal region thought to be deleted during tumorigenesis. One of the primers within the pair is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel in an ABI DNA sequencer and analyzed using GeneScan software 3.1 b3. Constitutive DNA from the patient's blood illustrates heterozygosity for this marker with amplicons represented by alleles 1 and 2. In DNA from the tumor, a single peak representing a typical homozygous pattern is observed. Thus there is LOH in tumor DNA. This loss signifies the loss of the second allele and also indicates the loss of this region on the chromosome. (See Figure 40-11.)

Color Plate 11 Electropherograms illustrating MSI in tumor DNA. Patient DNA is extracted from the peripheral blood and tumor tissue and amplified by PCR using an oligonucleotide primer pair specific for a microsatellite repeat locus. One of the primers within the pair is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel in an ABI DNA sequencer and analyzed by GeneScan software 3.1 b3. Constitutive DNA from the patient's blood illustrates heterozygosity for this marker with amplicons represented by alleles 1 and 2. In DNA from the tumor, in addition to constitutive alleles 1 and 2, amplicons representing DNA fragments of a different size are present; these indicate a change in repeat number for one of the alleles. Because of dysfunctional MMR enzymes, mistakes occurring during the replication of microsatellite repeat sequences resulting in expansions or contractions of the repeat number remain unrepaired. In this case, a contraction in the repeat number of allele 2 has occurred. (See Figure 40-12.)

Color Plate 12 Map of the human MHC region. The organization of the most important class I and class II genes of the MHC is shown, with approximate genetic distances given in thousands of base pairs (kb). Genes are ordered from telomere to centromere. Not shown are MHC class III genes, which map between class I and class II genes. (See Figure 41-2.)

transmitted or can expand to a full mutation allele and an offspring with fragile X syndrome.[426] Although rare, premutation alleles have been reported to undergo rather drastic contractions (82 to 33, 95 to 35, 145 to 43, 130 to 10, and 70 to 54).[84,426] The recent establishment of transgenic mice with CGG-repeat instability similar to that seen in humans should facilitate a better understanding of this phenomenon.[40,72] Premutation carrier females have a higher prevalence of premature ovarian failure (POF) as compared with females with normal CGG-repeat numbers in the general population.[120,441,513] Interestingly, full mutation carrier females and their noncarrier sisters appear to have no increased risk for POF.[523] Moderate CGG expansion seen in premutation carrier females may affect neurocognitive functioning related particularly to attention-related tasks.[51,545] Further, despite overexpression of *FMR1* in premutation carriers, the FMR1 protein, FMRP, appears to be significantly diminished, suggesting reduced translation efficiency.[299] Thus diminished FMRP levels in premutation carriers are negatively correlated with the repeat number, and overexpression of *FMR1* has a positive correlation with the repeat number. The risk of CGG expansion from a premutation to a full mutation allele is dependent on several factors including the number of pure uninterrupted CGG repeats, the number and position of interspersed AGG repeats, haplotype background, and less, well-characterized heritable factors.[93,155-157,251,427,525] In a large collaborative study among 13 laboratories in eight countries and involving >1500 premutation carrier females, the smallest premutation alleles shown to expand contained 59 repeats with no AGG interruptions.[426] Most data from humans suggest that expansion occurs before zygote formation, but the possibility of CGG expansion occurring very early in embryogenesis cannot be excluded.[356,392] Expansions of premutations to full mutations are largely confined to transmissions from females to offspring and are thought to occur from slippage during DNA replication of the lagging strand as a result of hairpin formation within the expanded CGG-repeat sequence.[190] Transmission of premutation repeat alleles in males remained stable in 16% of transmissions, decreased in size in 22% of transmissions, and expanded to a larger premutation allele in 62% of transmissions.[427] Premutation carrier fathers of premutation carrier females, or normal transmitting males, were previously thought to have a fairly normal phenotype with no clinical features of fragile X syndrome, although these males may have large ears and deficits in nonverbal tasks, which now too may be explained by reduced levels of FMRP.[299,343] Further, older premutation carrier males may exhibit a neurodegenerative syndrome characterized by progressive intention tremor, parkinsonism, and generalized brain atrophy.[230,285] Although FMRP is decreased, increased concentrations of *FMR1* transcript may represent a gain-of-function effect and possibly play a role in this premutation tremor and/or ataxia syndrome.[285] Recently, mice with premutation CGG repeats in the *FMR1* gene have been shown to have intranuclear inclusions in distinct regions of the brain, suggesting the role of the *FMR1* gene in this process and providing a possible explanation of clinical features observed in symptomatic premutation carriers.[631] Although expansion of a premutation to a full mutation is associated with maternal transmission, the sex of the fetus has no apparent effect on this process.[426]

The fragile X phenotype occurs following expansion of the CGG repeat, hypermethylation, and histone deacetylation of the adjacent CpG island in the promoter region of the *FMR1* gene, transcriptional silencing of the gene, and ultimately no production of FMRP.[47,115,456,560] *FMR1* mRNA is highly expressed in the testis and in the fetal and adult brain.[2,259] FMRP is an RNA-binding protein with two RNA-binding motifs and is associated with translating polyribosomes as a part of a large ribonucleoprotein complex.[35,176,534] Thus in cells from fragile X patients, hundreds of mRNAs exhibit abnormal translational profiles.[83] Recent studies on the *Drosophila* homologue of FMRP have indicated that FMRP mediates translation repression through RNA interference.[99,102,282,364] Males with full expansion alleles but incomplete methylation—"mosaic males"—may have severe mental retardation or a milder phenotype.[366,495] Although in vitro reactivation of the *FMR1* gene has been reported by inducing DNA demethylation and the reassociation of acetylated histones, reactivation of *FMR1* may not be enough to restore FMRP concentrations because transcripts with large repeats are not translated efficiently.[113,299]

Although CGG expansion is the mechanism of disease in greater than 99% of all cases, a point mutation within the gene (I304N) and deletions have also been reported to cause disease in males presenting with a clinical phenotype of fragile X syndrome.[132,194,235,565] DNA testing for fragile X syndrome using Southern blot analysis of peripheral blood enables detection of all possible genotypes (though not of all causes of fragile X as detected by cytogenetics [Figure 40-8]). PCR analysis with capillary electrophoresis is used to complement the testing by providing the precise CGG-repeat number. (It may also be used as the first test, but when it fails to resolve two alleles in a female or to identify an allele in a male the sample must be tested by Southern blot analysis because an expanded allele may be present that is too large to be amplified.) Chorionic villus samples or amniotic fluid can be tested, but the methylation pattern expected in adult tissue may be absent.

As expected, as the CGG-repeat length increases, the risk of expansion from a premutation to a full mutation in premutation carrier females increases. This information is most useful for determining the risk of an affected offspring during genetic counseling of a premutation carrier female. Although a woman with premutation CGG repeat of 55 to 59 is given about a 5% risk of expansion to a full mutation, a woman with a repeat length of 70 to 79 is given a 31% risk of expansion, and a woman with a CGG-repeat length >100 is given close to a 100% chance of expansion.[426] The American College of Human Genetics has published guidelines for testing in the laboratory.[354]

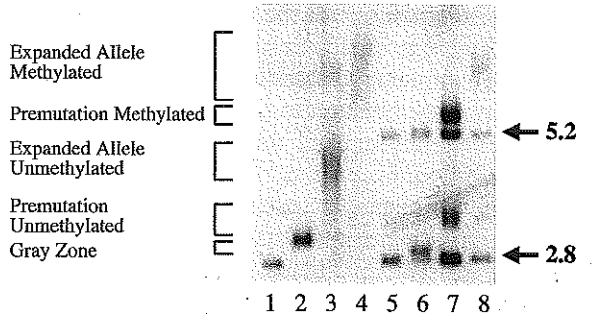


Figure 40-8 Southern blot analysis for the diagnosis of fragile X syndrome. Patient DNA is simultaneously digested with restriction endonucleases *EcoR*I and *Eag*I, blotted to a nylon membrane, and hybridized with a ^{32}P-labeled probe adjacent to exon 1 of *FMR1* (see Figure 40–7). *Eag*I is a methylation-sensitive restriction endonuclease that will not cleave the recognition sequence if the cytosine in the sequence is methylated. Normal male control DNA with a CGG-repeat number of 22 on his single X chromosome *(lane 1)* generates a band about 2.8 kb in length corresponding to *Eag*I-*EcoR*I fragments (see Figure 40–7). Normal female control DNA with a CGG-repeat number of 20 on one X chromosome and a CGG-repeat number of 25 on her second X chromosome *(lane 5)* generates two bands, one at about 2.8 kb and a second at 5.2 kb. *EcoR*I-*EcoR*I fragments approximately 5.2 kb in length represent methylated DNA sequences characteristic of the lyonized chromosome in each cell that is not digested with restriction endonuclease *Eag*I. DNA in lane 2 contains a *FMR1* CGG-repeat number of 90 and is characteristic of a normal transmitting male. The banding pattern observed in lane 3 is representative of a mosaic male with a single X chromosome with a full mutation (>200 repeats). However, the full mutation in some cells is unmethylated; in other cells, the full mutation is fully methylated, hence the term mosaic. In those cells in which the full mutation is unmethylated, digestion by both *Eag*I and *EcoR*I occurs, and in those cells in which the full mutation is fully methylated, digestion of the DNA by *Eag*I is inhibited. The banding pattern observed in lane 4 is diagnostic of a male with fragile X syndrome illustrating the typical expanded allele fully methylated in all cells. Lane 6 is characteristic of a female with a normal allele and a CGG-repeat number of 29 and a larger gray zone allele with a CGG-repeat number of 54. Lane 7 is the banding pattern observed from a premutation carrier female with one normal allele having a CGG-repeat number of 23 (band at about 2.8 kb) and a second premutation allele with CGG repeats of 120 to about 200 (band at about 3.1 kb). In premutation carrier females, in cells in which the X chromosome with the premutation allele is lyonized, the normal 5.2 kb *EcoR*I-*EcoR*I band is larger because of the increased CGG-repeat number and is about 5.5 kb in length. Lane 8 is diagnostic of a female with fragile X syndrome with one full expansion mutation allele that is completely methylated and transcriptionally silenced on one X chromosome but with a second normal allele with a CGG-repeat number of 33.

DISEASES WITH NONMENDELIAN INHERITANCE

Mitochondrial DNA Diseases

Mitochondria are organelles present in the cytoplasm of all eukaryotic cells of animals, higher plants, and some microorganisms. Mitochondria generate energy for the cellular processes by producing adenosine triphosphate (ATP) through oxidative phosphorylation (OXPHOS); they are important in maintaining calcium homeostasis and play a role in apoptosis.[191,453,468,535] The matrix of the mitochondrion is surrounded by a cardiolipin-rich inner membrane, and both are enclosed by a second outer membrane. Within the matrix are copies of the mitochondrial genome, mitochondrial deoxyribonucleic acid (mtDNA). Each mitochondria contains between about 2 and 10 copies of mtDNA, so with hundreds of mitochondria per cell, an estimated 10^3 to 10^4 copies of mtDNA exist within each cell, with brain, skeletal, and cardiac muscle having particularly high concentrations. The mtDNA is a double-stranded, circular molecule containing 16,569 base pairs that encodes 37 genes including: two ribosomal RNAs (rRNA), 22 transfer RNAs (tRNA), and 13 subunits required for the OXPHOS system, with seven belonging to complex I, one to complex III, three to complex IV, and two to complex V.[16,144] The majority of the subunits involved in the OXPHOS system are nuclear encoded as are several nuclear gene products that regulate mitochondrial gene expression.[225,611] Interestingly the mitochondrial genetic code is slightly different from the universal code. For example, in mtDNA, TGA codes for tryptophan rather than a termination codon, and all mitochondrial-encoded polypeptides contain codons requiring only the mitochondrial-encoded 22 tRNA molecules for translation rather than the 31 predicted by Crick's wobble hypothesis.[37] The high copy number of mtDNA per cell coupled with a small genome and unique sequence variations between individuals makes mtDNA sequence analysis an ideal tool for forensic studies.[372,587]

Mitochondria-related diseases can result from mutations in nuclear DNA or, as first reported in 1988, can result from mutations in the mitochondrial genome.* However, mitochondrial genetics are different from mendelian genetics in several aspects. First, all mtDNA is maternally inherited. With mature oocytes having the highest mtDNA copy number per cell at 10^5 and sperm having the lowest mtDNA copy number per cell at 10^2 after fertilization, sperm mtDNA is selectively degraded so that only maternal mtDNA remains. Thus if a mother is carrying an mtDNA mutation, it will be transmitted to all of her children, but only her daughters can transmit the disease to their offspring. Although this is considered the rule, paternal mtDNA inheritance has been reported and may result from incomplete degradation of sperm mtDNA in early embryogenesis.[514] If an mtDNA mutation arises, it will exist among

*References 223, 265, 511, 558, 616, 649.

a population of normal mtDNA. This coexistence of normal and mutant mtDNA copies within the same cell is referred to as *heteroplasmy* and is the second unique feature of mitochondrial genetics. Thirdly, during cell division, the proportion of normal and mutant mtDNA can shift as mitochondria and their accompanying genomes are partitioned into daughter cells. Thus in development and differentiation, the proportion of normal and mutant mtDNA can vary among cells and tissue within the body. Lastly the percentage of mutant mtDNA required within a cell, tissue, or organ system to result in a deleterious phenotype is referred to as the *threshold effect.* The threshold for disease varies between people, energetic requirements for tissue, and the mtDNA mutation. As is evident, genetic counseling for families with mtDNA disorders is complicated by the inability to accurately predict phenotype caused by the phenomena of heteroplasmy and threshold effect.[572]

Two types of mtDNA mutations exist, those that affect mitochondrial protein synthesis (tRNA and rRNA genes) and those within the protein-encoding genes themselves.[144,212] Direct sequencing of mtDNA is considered the gold standard for mutation detection, but this methodology may be unable to detect a low percentage of mutant mtDNA in a heteroplasmic state. Recently a simple and effective method referred to as temporal temperature-gradient gel electrophoresis coupled with PCR and DNA sequencing has been described that can detect heteroplasmic mutations as low as 4%.[637] Although mtDNA mutations are now associated with a significant number of inherited diseases, acquired mtDNA deletions are associated with the aging process, and mitochondrial dysfunction is associated with neurodegenerative diseases.[53,121,436,562] The most likely cause of somatic mtDNA mutations is via damage by oxygen free radicals produced as by-products of aerobic metabolism.[14,479]

Leber Hereditary Optic Neuropathy

Leber hereditary optic neuropathy (LHON) is the most common mitochondrial disease and the first linked to maternal inheritance through a mutation in the mtDNA.[616] LHON is characterized by bilateral subacute loss of central vision caused by focal degeneration of the retinal ganglion cell layer and of the optic nerve.[357] After initial symptoms, both eyes are usually affected within 6 months. Approximately 50% to 60% of males and only 8% to 32% of females who possess the mtDNA mutation will actually develop this optic neuropathy.[417] Nuclear-encoded factors that affect mtDNA expression, mtDNA products, or mitochondrial metabolism may modify the phenotypic expression of LHON.[418] Genetic counseling in LHON is complicated in that the amount of mutant mtDNA transmitted by heteroplasmic females cannot be predicted, and testing cannot predict which individuals will develop visual symptoms.[275]

LHON is a disorder caused by OXPHOS deficiency. Although more than 27 mutations have been associated with this disease, mtDNA mutations G3460A, G11778A, and T14484C represent 95% of those identified.[353] Mutation G11778A was the first described, is the most common, and accounts for at least 50% of cases. In most affected individuals, LHON mutations appear to be homoplasmic, with only mutant mtDNA detected, but in 15% of cases, the mutations are heteroplasmic, with a mixture of both normal and mutant mtDNA detected.[536,608] Each of the common mutations affects a subunit of the nicotinamide adenine dinucleotide: ubiquinone oxidoreductase in complex I of the OXPHOS pathway. The mechanism by which these mutations cause the LHON phenotype is not well understood.[418]

Clinical DNA testing for these mutations is widely available and typically involves PCR amplification coupled with restriction endonuclease analysis and gel electrophoresis.[18,398] If the patient's mtDNA is negative for the three common mutations, testing for other mtDNA mutations associated with LHON should be considered.[167,398] DNA sequencing of all of the mtDNA-encoded complex I genes or of the entire mitochondrial genome may be required but should be employed only when clinical suspicion for LHON is high.[18,418]

Leigh Syndrome

Leigh syndrome (LS), or subacute necrotizing encephalomyelopathy, is a progressive neurodegenerative disorder that eventually leads to death. In contrast to LHON, patients present within the first few years of life with hypotonia, failure to thrive, psychomotor regression, ocular movement abnormalities, ataxia, and brainstem and basal ganglia dysfunction caused by severe dysfunction of mitochondrial energy metabolism. The clinical phenotype for LS is variable in patients with the same pathogenic mtDNA mutation and largely results from differences in the percentage of mutant mtDNA among organs and tissues within an individual[98,580] (Figure 40-9).

LS exhibits genetic heterogeneity, with disease-causing mutations identified in both nuclear and mtDNA, making both mendelian and maternal patterns of inheritance possible for this syndrome.[143] Mutations in mtDNA genes *ATPase6* (complex V), ND5 (complex I), and $tRNA^{Lys}$, or nuclear-encoded genes affecting pyruvate dehydrogenase or respiratory chain enzyme complexes I, II, and IV have been reported.* The most common biochemical abnormality associated with LS is deficiency of cytochrome c oxidase caused by defects in the assembly of complex IV. The protein products from the *SURF-1* and *COX 10* genes play an important role in the assembly of complex IV, and mutations in these genes follow an autosomal recessive mode of inheritance.

Clinical testing for mitochondrially inherited LS uses direct sequencing of mtDNA-encoded genes. Because of the genetic heterogeneity of nonmitochondrially inherited LS and the need for mutation screening for a number of genes,

*References 7, 76, 363, 451, 561, 568, 574, 577, 591-592.

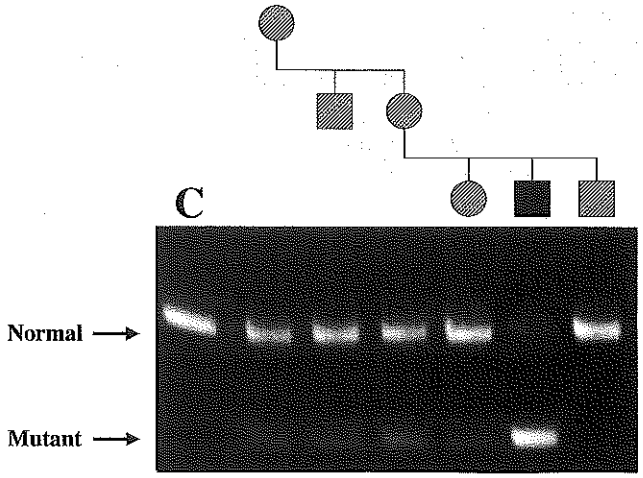

Figure 40-9 Detection of varying degrees of heteroplasmy for mtDNA mutation A8344G in a family with Leigh syndrome.[441] Mitochondrial DNA was extracted from a peripheral blood specimen from an affected male with Leigh syndrome and from family members. Mitochondrial DNA was amplified using an oligonucleotide primer pair that flanks mitochondrial mutation A8344G. The A-to-G base substitution creates a *Nae* I recognition site (GCCGGC), which is not present in normal control mtDNA (C). Amplicons from each member of the family and the control were digested with *Nae* I and subjected to gel electrophoresis. The virtual absence of undigested amplicons in the affected male indicates the presence of almost 100% mutant mtDNA in the cells from this specimen and coincides with the severe phenotype of Leigh syndrome in this patient.[441] In contrast, his sister, mother, and grandmother with 30%, 40%, and 20% mutant mtDNA suffer only from migraine headaches. His uncle, with 30% mutant mtDNA present, suffers with attention-deficit-hyperactivity disorder and learning disabilities. Heteroplasmy, or variation in the percentage of normal and mutant mitochondria, largely explains the observed phenotypic differences in this family. *(Figure courtesy of Thomas W. Prior, Ph.D., Depts of Pathology and Neurology, Ohio State University, Columbus, Ohio.)*

clinical testing for LS is limited and not currently available in the United States.[196]

IMPRINTING

Imprinting refers to the differential marking or "imprinting" of specific paternally and maternally inherited alleles during gametogenesis, resulting in differential expression of those genes. Such imprints on the DNA during gametogenesis must be maintained through DNA replication in the somatic cells of the offspring, must be reversible from generation to generation, and must influence transcription. DNA methylation is the primary mechanism for genomic imprinting. The number of imprinted genes in the human genome is estimated to be less than 200, and most are clustered around imprinting control centers. Alterations in normal imprinting patterns can result in disease.

Prader-Willi and Angelman Syndromes

Prader-Willi syndrome (PWS) is characterized by hypotonia, obesity, short stature, small hands and feet, motor and mental retardation, and hypogonadism. The syndrome is also associated with specific behavioral and psychopathological characteristics, which present challenging management issues.[140,412] The disorder is relatively frequent, with an incidence of 1 in 10,000 to 15,000. Angelman syndrome (AS) is characterized by severe mental retardation, inappropriate bouts of laughter, absence of speech, gait ataxia, frequently microcephaly, and seizures. The incidence of AS is estimated at about 1 in 12,000 to 20,000. As apparent from their characteristic physical findings, PWS and AS are clinically distinct syndromes; yet each results from one of several possible genetic changes involving chromosomal region 15q11-q13 (long arm of chromosome 15 within banding regions 11 and 13).[409,419] Within this 4-megabase (Mb) region, 2 Mb are imprinted, with gene expression dependent on parental origin. PWS results from the loss of paternally expressed genes in this region, and AS results primarily from the loss of a maternally expressed gene in this region.

The primary candidate gene for PWS is the paternally expressed *SNURF-SNRPN* locus.[206,419,437] There is extensive DNA methylation at the CpG island upstream from this locus on the maternal allele resulting in transcriptional silencing of this locus. The *SNURF-SNRPN* is a complex locus that contains a *cis*-acting regulatory region referred to as the imprinting center (IC), which controls resetting of parental imprints in the 15q11-13 region during gametogenesis and two polypeptides, SmN and SNURF, and a small nucleolar RNA (snoRNA), *HBII-13.** SmN is involved in mRNA splicing in the brain, and SNURF (*SNRPN* Upstream Reading Frame) is found in the nucleus, contains 71 amino acids, may bind RNA, and has a C-terminal motif similar to ubiquitin. HBII-13 is encoded from within intron 12 of SNURF and modifies RNA, perhaps mRNA and rRNA and snRNA. In addition, multiple imprinted and paternal-only expressed genes have also been identified in this region including *NDN,* which encodes necdin, a protein important for neuronal differentiation and a suppressor for cell proliferation; *IPW,* which encodes a 2.2 kb RNA but is not translated into a polypeptide; *MKRN3,* which encodes makorin ring zinc-finger protein 3; and *MAGEL2,* which encodes melanoma antigen-like gene 2.[295,328,406,624] These expressed genes may have additive roles in the phenotype of PWS.[420] The loss of normally expressed paternal genes in 15q11-q13 resulting in PWS can occur by several mechanisms. Most commonly, PWS (65% to 70%) results from a de novo deletion encompassing this area following unequal homologous recombination involving repeated homologous sequences in this region. The subsequent zygote would be monosomic for these genes by possessing only the maternal copy. Alternatively, 25% to 30% of PWS is caused by uniparental disomy.

*References 62, 103, 214, 431, 501, 559.

In this scenario, although two copies of the genes located in 15q11-q13 exist, both are maternal in origin, arising in most cases from meiosis I nondisjunction and subsequent loss of the third, paternal-derived chromosome 15 through mitotic loss postzygotically. This mechanism of chromosome loss rescues the zygote from trisomy 15, a condition that is incompatible with life.[486] Although in this situation the fetus is genetically complete with two chromosome 15s (disomy), both chromosomes are, however, from the same parent (uniparental) with a loss of paternal-expressed loci in the critical imprinted region 15q11-q13. In about 5% of cases, PWS can result from microdeletions encompassing the paternal IC. Or in some cases, there is no detectable DNA mutation, but rather there is an abnormal imprint.[86-87] A microdeletion containing the IC prevents this *cis*-acting control center from resetting the imprint in the germline. These mutations, if present on the maternal chromosome of phenotypically normal fathers, will be transmitted to offspring as the paternal chromosome and result in a child with PWS. Lastly, less than 1% of PWS cases are caused by chromosomal rearrangements disrupting the genes in the 15q11-q13 region.[557]

The primary maternally expressed gene in the PWS and/or AS critical region is *UBE3A*, although a second gene, *ATP10C*, has been shown to display predominantly maternal expression in brain and lymphocytes.[304,374] The *UBE3A* gene is almost exclusively expressed in the brain, contains 16 exons, and encodes an E3 ubiquitin ligase involved in the ubiquitination pathway for degradation of a diverse range of protein substrates.[260] The lack of ubiquitination could result in the inability to degrade or functionally alter targeted proteins. Similar to PWS, 70% of AS patients have a deletion of the critical 15q11-q13 region. However, unlike PWS in which a deletion on the paternal allele causes PWS, in AS a deletion encompassing this region on the maternal chromosome 15 yields the clinically distinct AS phenotype. Recently an inversion mutation was identified in the mother of four of six AS patients with a deletion in this region.[203] It is likely that the presence of these inverted DNA sequences in these women predisposed this region to deletions in their offspring by interfering with normal homologous synapses, or pairing of homologous chromosomes, during meiosis. AS patients with a deletion have a more severe phenotype possibly because of haploinsufficiency of nonimprinted *UBE3A* adjacent and co-deleted genes. In 7% of AS patients, phenotypic expression of the syndrome occurs as a result of uniparental disomy because of the inheritance of two copies of a paternal chromosome 15 in contrast to the normal inheritance of one paternal and one maternal allele. As a consequence, with both paternal *UBE3A* genes silenced, there is no functional UBE3A protein. In 3% of AS patients, an imprinting defect has been described.[86,270] A cytogenetic rearrangement has been detected in about 1% of AS cases, and in 11% of cases, a mutation in the *UBE3A* gene itself has been reported.[164] Although these mutations can arise de novo, they can be silently transmitted through several generations. For example, if a *UBE3A* mutation rose de novo on a paternal allele transmitted to a son, the son could transmit the mutation to a son or daughter to result in a normal phenotype. However, although this son could again transmit the silenced *UBE3A* mutation to his offspring, his sister could donate her mutated *UBE3A* paternally derived allele to her offspring, and the child would have AS. Lastly, in about 11% of AS patients, the etiology of the disease has not been established.

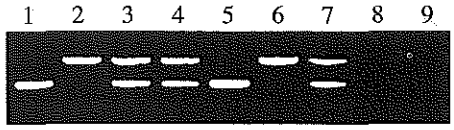

Figure 40-10 Methylation-specific PCR assay for the diagnosis of PWS and AS. Extracted DNA is treated with sodium bisulfate before amplification using multiplex PCR and oligonucleotide primers specific for modified DNA.[482] Normal individuals show amplicons representing their methylated maternal allele and amplicons from their unmethylated paternal allele. PWS patients show only the maternal allele and AS patients show only the paternal allele. Results observed following PCR amplification and gel electrophoresis of patients referred for PWS and AS testing. Patient DNA with patterns diagnostic of AS *(lanes 1 and 5)*, PWS *(lanes 2 and 6)*, and patients referred for AS or PWS but who have normal methylation patterns *(lanes 3 and 4)* are shown. Normal control DNA patterns and a negative control reaction in which no template DNA was added are indicated in lanes 7 and 8, respectively. No amplification products are observed in unmodified normal control DNA *(lane 9)*, illustrating the specificity of the PCR primers specifically for sodium bisulfate modified DNA. *(Figure courtesy of Jack Tarleton, Ph.D., Director of Genetics Laboratory, Fullerton Genetics Center, Mission Hospitals, Asheville, N.C.)*

Diagnostic testing for individuals suspected of having AS or PWS can involve a variety of methodologies.[13] Further, determining the genetic mechanism for the cause of the disease is important for determining recurrence risks for the family.[89] Under most circumstances, initiating testing with methylation-specific PCR (mPCR) is one scenario that can be used and may be the most cost-effective approach[386] (Figure 40-10). In methylation-specific PCR, genomic DNA is treated with sodium bisulfite before PCR to convert unmethylated cytosine residues to uracil without altering the methylated cytosine residues (those silenced in the 15q11-13 region). The subsequent PCR reactions use oligonucleotide primers specific to DNA strands that contain either uracil (unmethylated) or cytosine (methylated).[312,603] Methylation-specific PCR provides a rapid and reliable diagnostic test to rule out PWS or AS. If the result is negative, >99% of PWS and about 80% of AS patients can be ruled out. PWS patients with a chromosomal rearrangement disrupting the genes in this area will not be identified by this test. Similarly, AS patients with a *UBE3A* mutation, a chromosome rearrangement disrupting the genes in the region, or AS resulting from an unknown etiology will not be diagnosed with this

TABLE 40-2 Molecular Mechanisms and Tests for Prader-Willi and Angelman Syndromes*

Molecular Mechanism	Angelman Syndrome (Frequency)	Prader-Willi Syndrome (Frequency)	Methylation-Specific PCR Result	Possible Detection Methods
Deletion (~4Mb) of chromosome 15q11-13	70% (maternal)	65%-70% (paternal)	Abnormal	High-resolution cytogenetics or FISH
Uniparental disomy	7% (paternal)	25%-30% (maternal)	Abnormal	PCR for microsatellite analysis
Imprinting center defect	3%	~5%	Abnormal	IC sequencing
UBE3A mutation (specific to AS)	11%	N/A	Normal	UBE3A sequencing
Chromosomal rearrangement in chromosome 15q11-13 region	<1% (maternal)	<1% (paternal)	Normal	High-resolution cytogenetics or FISH
No detectable abnormality	~11%	Very few cases	Normal	N/A

*Modified from a table prepared by Allison Presley, MD, University of Virginia.

methodology. However, if the result is positive, FISH studies can be performed to detect a deletion within 15q11-13, and/or uniparental disomy DNA testing should be done to determine the genetic mechanism of disease for appropriate genetic counseling of the family. The mechanisms and tests for PWS and AS are summarized and contrasted in Table 40-2.

Complex Diseases

A complex or multifactorial inheritance pattern indicates interaction of one or more genes with one or more environmental factors. Multifactorial diseases can be more prevalent in some families with several affected family members, but the disease does not follow typical mendelian inheritance patterns. Disease may present in multiple family members because of the sharing of similar disease-predisposing alleles and often the sharing of similar daily habits, routines, and diet. The degree of genetic and environmental contribution to a disease process varies among complex diseases, and identification of the causative genetic and environmental factors is challenging. Further, it is difficult to assess the relative importance of genetic and environmental influences in the development of a disease, though twin studies are often used. Among twins who were raised together, a greater concordance of disease among monozygotic (MZ) twins—who share all of their genes—than in dizygotic (DZ) twins, who share 50% of their genes, provides strong evidence of a genetic component to the disease. Conversely, disease concordance <100% in MZ twins is strong evidence that nongenetic factors play a role in the disease. Examples of largely adult-onset complex diseases include type 1 diabetes, multiple sclerosis, Parkinson disease, hypertension, alcoholism, and thrombophilia.

Thrombophilia

Deep vein thrombosis (DVT) occurs in about 1 per 1000 individuals, and complications from DVT, including pulmonary embolism, account for about 50,000 deaths per year.[531] Venous thrombosis is caused by a disruption of normal hemostasis caused by the interaction of one or more genes and environmental factors and/or acquired conditions, including use of oral contraceptives, trauma, obesity, immobility, pregnancy, age, or surgery.[250] Although the protein products of many genes are involved in the anticoagulation and coagulation pathway and are involved in the regulation of hemostasis, mutations in the factor V and prothrombin genes are associated with DVT, represent the most frequent genetic cause of thrombophilia, and are common in the population.[58,457] Further, patients with both mutations have an increased risk of a recurrent DVT and may require different management than patients with only one of the two mutations.[134] Consistent with that of a complex disease, despite the presence of these mutations and some environmental and/or acquired factors, it is impossible to predict a patient's clinical course even within members of the same family. Thus venous thrombosis illustrates our lack of understanding in the interaction of known and uncharacterized risk factors in predisposition to a complex disease.

Activated protein C in conjunction with its cofactor, protein S, plays a key role in the anticoagulant system by inactivating membrane-bound factors Va and VIIIa. The inability to inactivate procoagulant factors Va or VIIIa could disturb hemostasis, heighten the coagulation pathway, increase the generation of thrombin, and promote clot formation. In 1993 Dahlback reported familial thrombophilia caused by resistance to activated protein C (APC).[129] In 1994

Bertina et al observed linkage of the factor V gene and the APC resistance phenotype and reported a G-to-A base substitution at nucleotide 1691 in exon 10 of the factor V gene.[58] This nucleotide change results in an arginine-to-glutamine substitution at codon 506 (R506Q) in the factor V protein. Cleavage at the arginine residue at codon 506 by APC is the initial step of inactivation of the activated factor V protein, causing it to display a decreased affinity for factor Xa.[128,297,358] As a result, there is reduced efficiency in catalyzing the activation of prothrombin to alpha-thrombin.[358] However, substitution with a glutamine residue at this site prolongs inactivation of this molecule by APC by approximately tenfold, thereby shifting the balance of hemostasis to favor coagulation and increasing thrombin production.[248] Interestingly, this mutation is quite common in the Caucasian population of Northern European descent, with a frequency of 3% to 5%, but is essentially absent in Asian, African, or Australian populations.[58,268,474,480] This phenomenon is thought to result from the fact that the G-to-A mutation occurred as a single event approximately 21,000 to 34,000 years ago after the evolutionary divergence of non-Africans from Africans and of Caucasians from Mongoloids.[655] Heterozygous carriers have a 7.9-fold increased relative risk of thrombosis compared with a ninety-onefold increased risk for homozygotes.[491] The risk for thrombosis is increased in the presence of other genetic or environmental and/or acquired factors.[70,162,197,362,596] The mean age of onset of symptoms associated with thrombosis is 44 years for heterozygotes and 31 years in homozygotes.[491] Further, although transmitted as a dominant trait—with carriers of this mutation possessing a lifelong risk—and because thrombophilia is a complex disease resulting from the interaction of both genetic and environmental and/or acquired factors, many heterozygote carriers can remain asymptomatic.[216,491]

In 1996 Poort et al described a genetic variant in the 3′-untranslated region of the prothrombin gene in 18% of patients with a documented family history of venous thrombosis.[457] In a population-based case control study, this common allele (G-to-A base substitution at nucleotide 20210) increased the risk of venous thrombosis 2.8-fold and was associated with increased plasma prothrombin (>1.15 kU/L). The risk of venous thrombosis is increased sixteenfold in G20210A carriers using oral contraceptives, and the risk of cerebral vein thrombosis increases 149-fold in G20210A carriers using oral contraceptives.[361-362] In the Caucasian population, this base substitution is present in 6.2% of patients with venous thrombosis compared with 2.3% of controls. This allele is thought to be largely confined to the Caucasian population, because it was not detected in 170 Japanese, nor 80 Asians, although it was reported in 1 of 256 African-American infants and 2 African-American patients with venous thrombosis.[142,185,283] Similar to the origin of factor V mutation G1691A, it is thought that the G20210A base substitution occurred as a single event after the divergence of Africans from non-Africans and of Caucasoid from Mongoloid subpopulations.[656] Prothrombin, also referred to as factor II, is the precursor of thrombin and plays a primary role in fibrin production and clot formation. The G-to-A substitution increases the processing of the 3′-end of the pre-mRNA and thus functions as a gain-of-function mutation, culminating in increased mRNA accumulation and increased synthesis of protein.[195] This aberration of RNA metabolism results in increased synthesis of prothrombin and can enhance clot formation. Note that the substitution does not change the amino acid sequence of prothrombin.

Inherited together, G1691A (factor V) and G20210A (factor II, prothrombin) convey at least a twentyfold increased risk for a venous thromboembolic event (VTE). They are commonly seen together in thrombophilia patients thus supporting the additive genetic effect associated with complex diseases.[41,101,134,160,576]

DNA testing for G1691A and G20210A in clinical laboratories is performed by any one of several methodologies with those most commonly reported being invasive cleavage of oligonucleotide probes (Invader assay), PCR coupled with restriction-endonuclease digestion and gel electrophoresis, and real-time PCR.[58,238,327,457,627] Many other techniques have been described.[33,67,150,256,443] Any testing platform is acceptable for clinical use as long as the procedure has been properly validated in the laboratory and follows appropriate quality assurance guidelines.[221] Standards for reporting of molecular diagnostic tests have been published as well, but many laboratories reporting factor V mutation results do not follow these guidelines.[17,410]

DNA-based testing for factor V may be requested on a patient following the factor V Leiden-specific functional assay (Coatest APC resistance, Chromogenix AB, Sweden) to confirm the diagnosis and to distinguish between heterozygotes and homozygotes. Similarly, DNA testing can be ordered in place of the functional assay especially for patients with lupus anticoagulant and a markedly prolonged baseline aPTT (which may interfere with the assay), or in family members of G1691A-positive patients.[648] Since there may be multiple causes of a thrombotic event, factor V and prothrombin testing is especially recommended in patients in whom a high clinical suspicion exists, such as patients with: (1) venous thrombosis or pulmonary embolism and age under 50; (2) venous thrombosis at an unusual site (hepatic, mesenteric, portal, or cerebral veins); (3) recurrent VTE; (4) VTE and a strong family history of thrombotic disease; (5) VTE in pregnant women or women taking oral contraceptives; or (6) relatives who had VTE at age less than 50 years.[221,367,462]

Benefits from DNA testing include the identification of individuals at risk for recurrent events, especially in situations that predispose to thrombosis, such as oral contraceptive use, management of pregnancy complications, or hormone replacement therapy.[135,462] In addition, DNA testing enables the identification of at-risk family members. Screening is not recommended for populations or newborns nor is prenatal screening recommended. Although factor V

R506Q represents the genetic factor in thrombophilia in greater than 50% of families with thrombosis, inherited defects in protein C, protein S, and antithrombin are detectable in approximately 10% to 15% of families with venous thrombosis. These latter, less common deficiencies can be diagnosed through laboratory assays and do not typically involve DNA testing because of the heterogeneity of mutations in these genes.[43,73,476] Mutations at two other factor V arginine-cleavage sites have been reported, but these mutations are very rare and are not part of routine DNA testing in patients.[107,632]

Inherited Breast Cancer

Mutations in the two major breast cancer genes, *BRCA1* and *BRCA2*, predispose patients to breast and ovarian cancer and to prostate and colon cancer (*BRCA1*) or pancreatic cancer (*BRCA2*). The incidence of mutations in these genes within the population is estimated to be between 1 in 500 and 1 in 1000.[563] However, the combined frequency of three common mutations in the Ashkenazi Jewish population is as high as almost 3%.[483] Breast carcinoma is second only to lung carcinoma as a cause of cancer-related death among women in the Western hemisphere, but familial breast cancer accounts for only 5% to 10% of all cases. *BRCA1* and *BRCA2* mutations are present in only about 20% of familial cases and are often associated with a younger age of onset. Recent studies suggest that the progression rate of breast neoplasia is accelerated in women who carry *BRCA1* or *BRCA2* mutations compared with other patients who have breast carcinoma with or without a family history.[6] In families in which breast cancer is segregating, but no *BRCA1* or *BRCA2* mutation has been detected, additional genes that predispose to breast cancer are likely but have yet to be identified.[600] The inability to identify breast cancer susceptibility genes in these families may reflect: (1) genetic heterogeneity in the family with mutations in several genes, (2) low penetrance of these mutations, making it difficult to distinguish family members without mutation from asymptomatic carriers in the studies, (3) an autosomal recessive mode of inheritance, or (4) breast cancer acting as a complex disease that results from the interaction of both several genes and environmental factors, thereby making it difficult to tease out the genetic component of the disease. Recently developed gene-expression assays of tumor tissue may be instrumental for classification of these families into subsets, aiding studies aimed at determining the molecular origin of these cancers.[247] Mutations in tumor-suppressor genes *TP53* or *ATM* are also associated with "familial" cancer, including breast cancer in mutation-positive females.[284,334]

Mutations in *BRCA1* and *BRCA2* are inherited in an autosomal dominant fashion, with offspring of known carriers or of affected patients possessing a 50% chance of inheriting the predisposing cancer gene mutation. Inheritance of the mutation does not convey a certainty of developing cancer nor indicate the type of cancer or the age of onset.[333] The average cumulative risk of breast cancer for mutations in either BRCA1 or BRCA2 is about 27% to age 50 and 64% to age 70.[516] Both environmental and genetic factors play a role in the development of breast or other cancers in mutation-positive patients as does the type of DNA mutation in *BRCA1* or *BRCA2*.[193,407-408,516]

Using DNA linkage studies, Hall et al mapped the gene for early onset familial breast cancer to 17q21 (long arm of chromosome 17 banding region 21).[231,409] In 1994 *BRCA1* was cloned and later confirmed by several other investigators as the susceptibility gene in breast and ovarian cancer kindreds.[100,188,377] The *BRCA1* gene spans 80 kb, is composed of 24 exons, 22 encode the 7.8-kb mRNA that is translated into a protein of 1863 amino acids. The large exon 11 (3427 bp) accounts for 61% of the coding portion of the gene. In families in whom linkage to *BRCA1* was excluded, a second susceptibility locus at 13q12-13 (long arm of chromosome 13 within banding region 12 and 13), *BRCA2*, was proposed and subsequently cloned.[409,567,638-639] The *BRCA2* gene, unrelated in sequence to *BRCA1*, spans 70 kb, contains 26 exons, encodes an 11.5-kb mRNA, and is translated into a protein of 3418 amino acids. *BRCA1* and *BRCA2* are considered tumor-suppressor genes requiring inactivation of both alleles for progression to neoplasm. In a patient with familial breast cancer, a mutant allele is inherited, and the second allele—the patient's wild-type allele—is inactivated through somatic mutation. BRCA1 and BRCA2 proteins are multifunctional, interacting with numerous other proteins in complex and separate systems involved in response to DNA damage, regulation of transcription, remodeling of chromatin, and regulation of cell growth.[130,585,605]

Mutations in *BRCA1* and *BRCA2* are heterogeneous and located throughout each gene, with more than 1600 identified to date.[79,196] Interestingly the range of mutations varies greatly among different populations, with founder mutations observed in many ethnic groups.[339,413,563] In Ashkenazi Jewish breast and ovarian cancer families, mutations 185delAG and 5382insC are the ones primarily observed in *BRCA1*, and in families in whom these mutations are not present, the identification of other *BRCA1* mutations is rare.[455] In addition, *BRCA2* mutation 6174delT has been observed in 6 of 80 (8%) Ashkenazi Jewish women diagnosed with breast cancer before age 42 as compared with 0 of 93 non-Jewish women diagnosed with breast cancer at the same age.[416] *BRCA1* mutation 943ins10 is an ancient founder mutation of West African origin, and mutation 2804delAA, estimated to have occurred about 32 generations ago, is seen in Dutch and Belgian families.[369,432,445] The *BRCA2* mutation 999del5 is common in the Icelandic population, whereas the founder *BRCA2* mutations S2835X and 5802del4 are common in Japanese breast cancer families.[278,293] In contrast, *BRCA1* and *BRCA2* mutations are less commonly associated with familial breast cancer in Taiwanese and Chinese populations.[110,650]

Testing for disease-associated mutations is made difficult by the heterogeneity of disease-causing mutations and the complexity of the *BRCA1* and *BRCA2* genes. Moreover, the

clinical significance of some observed variants may be unknown and in some cases may be benign.[137] Interestingly the majority of *BRCA1* and *BRCA2* disease-associated mutations result in premature truncation of the protein and thus a loss of function. For this reason, the protein truncation test (PTT) is often employed as a screening method for mutation detection. In this methodology, multiple PCR primer pairs are designed to span the gene with each primer pair, including one primer that includes an RNA polymerase promoter and a translation initiation sequence. The resulting amplicons are incubated in an in vitro translation system, and the synthesized proteins are subjected to sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis for detection of truncated proteins.[263]

In addition to PTT, various other screening techniques have been described to provide maximum sensitivity in mutation detection, yet high throughput of specimens. Other common screening assays include microarrays, denaturing high-performance liquid chromatography (DHPLC), single-strand conformation polymorphism (SSCP), denaturing gradient gel electrophoresis (DGGE), heteroduplex analysis (HA), and fluorescence assisted mismatch analysis (FAMA).[228,522] More recently, other unique methods have been described as well, including allele-specific gene expression analysis (AGE), multiplex ligation-dependent probe amplification (MLPA), and restriction endonuclease fingerprinting, single-strand conformation polymorphism coupled with capillary electrophoresis.[311,389-390]

Although screening assays can detect DNA perturbations, DNA sequence (DS) analysis is required for precise identification of the base or bases involved. In many instances, a combination of screening methods is used, thereby reducing the region of the gene that requires DNA sequencing analysis. In addition, since founder mutations within various populations exist, information regarding the ethnicity of the patient may be valuable in determining the strategy for analysis, employing a method to detect those mutations most common in that population. An alternative approach is to eliminate screening of the gene and rather perform direct DS analysis of the *BRCA1* and *BRCA2* genes on each specimen. A large study concluded that DS is not the most cost-effective method available for testing.[522]

Clinical testing for *BRCA1* and *BRCA2* is primarily performed on women with breast cancer and a strong family history of breast and/or ovarian cancer or on presymptomatic women with a strong family history of breast and/or ovarian cancer for which prior identification of a *BRCA1* or *BRCA2* mutation in the family may or may not have occurred. The impact of genetic testing on these patients has been well evaluated.[75,234,371] The likelihood of identifying a *BRCA1* or *BRCA2* mutation in a patient is increased to 10% or greater if: (1) breast cancer was diagnosed in two women in the family before the age of 50; (2) breast cancer was diagnosed in women in the family before age 50, and ovarian cancer was detected in one or more women in the family; (3) breast cancer was diagnosed after the age of 50 in one woman, and ovarian cancer was detected in two or more women in the family; (4) ovarian cancer is present in two or more family members; (5) male breast cancer is present, and breast or ovarian cancer is present in the family.[488]

In presymptomatic cases, extensive genetic counseling addressing both the positive and possible negative aspects of genetic testing must be discussed with the patient before genetic testing is undertaken. Counseling often involves participation of family members, usually spouses. Based on the family history, the genetic counselor should inform the patient of the likelihood that a *BRCA1* or *BRCA2* mutation could be segregating in the family, the risk of disease(s) associated with mutations, and an overview of prevention and surveillance options available for mutation carriers.[487] Counseling may be needed for psychological issues, including the fear of cancer or medical procedures, past experiences involving loved ones with cancer, feelings of guilt about possibly transmitting a cancer-causing gene to children, and discrimination by employers or insurers if a positive test result is disclosed.[74] The continued anxiety and uncertainty with some test results should be discussed as well. For example, in some instances when DNA from an affected family member is not available for testing, the presymptomatic patient must clearly understand that a negative result could imply the inability to detect the specific *BRCA1* or *BRCA2* gene mutation segregating in the family and would not exclude the possibility of a mutation in another breast cancer–susceptibility gene that may be present in the family. Further, the possibility of identifying a DNA alteration of unclear significance and the associated uncertainty and anxiety resulting from such a finding must also be discussed. A U.S. patent has resulted in clinical testing for *BRCA1* and *BRCA2* being available exclusively at one location within the United States; both false-negative test results and variants of uncertain significance are possible.[196] The absolute control of diagnostic testing of these genes for patient care is an issue of much debate.[52]

Once an asymptomatic, mutation-positive woman has been identified, she may wish to undergo prophylactic bilateral mastectomy, oophorectomy, or specialized surveillance and prevention strategies for the early detection of both breast and ovarian cancer. The risk of breast cancer can be significantly lower in women choosing prophylactic surgery than in those opting for increased surveillance.[370]

Inherited Colon Cancer

Colorectal cancer (CRC) is the second leading cause of cancer death in the United States, with about 5% of cases associated with inherited mutations linked to colon cancer syndromes. The molecular basis of sporadic and inherited CRC involves two distinct pathways, one of chromosomal instability and one associated with microsatellite instability. The original model of chromosome instability proposed in 1990 to explain the pathogenesis of most sporadic tumors (~85%) has been further characterized to reveal a complex chain of events whereby normal colon lining (mucosa) is transformed

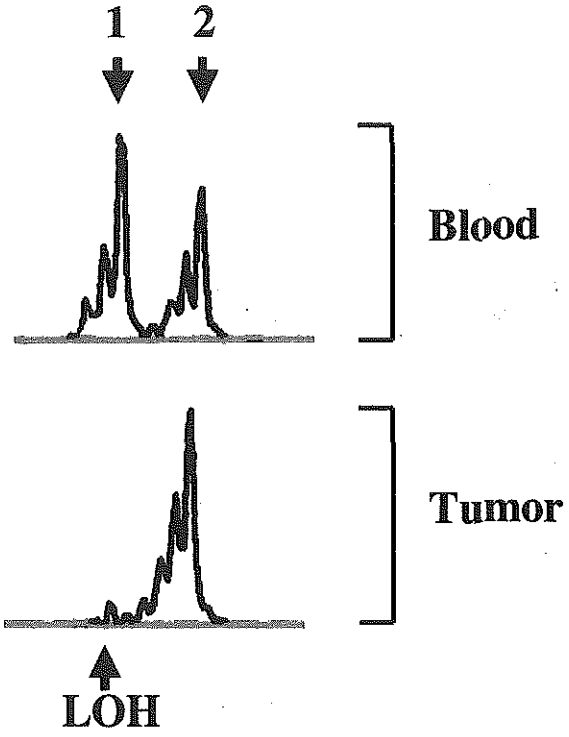

Figure 40-11 Electropherograms illustrating loss of heterozygosity (LOH) in tumor DNA. Patient DNA is extracted from the peripheral blood and tumor tissue and amplified by PCR using an oligonucleotide primer pair specific for a polymorphic, microsatellite repeat locus contained within the chromosomal region thought to be deleted during tumorigenesis. One of the primers within the pair is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel in an ABI DNA sequencer and analyzed using GeneScan software 3.1 b3. Constitutive DNA from the patient's blood illustrates heterozygosity for this marker with amplicons represented by alleles 1 and 2. In DNA from the tumor, a single peak representing a typical homozygous pattern is observed. Thus there is LOH in tumor DNA. This loss signifies the loss of the second allele and also indicates the loss of this region on the chromosome. (See Color Plate 10.)

into adenomatous and then into malignant mucosa via the inactivation of tumor-suppressor genes and the activation of genes involved in tumor cell proliferation.[96,171]

The *chromosomal instability (CIN) pathway* begins with the loss of function of the adenomatous polyposis coli (*APC*) tumor-suppressor gene product, most often because of a somatic inactivating gene mutation on one allele followed by a chromosomal deletion encompassing the second *APC* allele and adjacent flanking DNA on chromosome 5q (Figure 40-11 and Color Plate 10). Since *APC* is involved early in the tumorigenic process, it has been referred to as the "gatekeeper."[303] The cascade of events proceeds with continued activation of the *KRAS* (Kirsten rat sarcoma virus) protooncogene on 12p12.1 (short arm of chromosome 12 banding region 12.1) through somatic gene mutations (most frequently occurring in codons 12, 13, or 61), which in the presence of *APC* inactivation increases growth and proliferation of the cell.[409] Subsequent inactivation of the tumor-suppressor gene *DCC* (deleted in colon cancer) and frequent loss of adjacent tumor-suppressor genes on 18q (long arm of chromosome 18) including SMAD4 and SMAD and the inactivation of tumor-suppressor gene *TP53* on 17p (short arm of chromosome 17) are identified in late adenoma and carcinoma.[409]

The *microsatellite instability (MSI) pathway* in sporadic CRC arises from mutations or altered expression of genes involved in DNA mismatch repair (MMR)[255,381,528] (Figure 40-12 and Color Plate 11). As a result of an altered and thus dysfunctional MMR system, DNA replication errors, primarily within microsatellite repeats or repetitive sequences, remain uncorrected and accumulate. Although expansion or contraction of the microsatellite-repeat number is of little significance in much of the noncoding areas of the genome, changes within coding regions of the genome and specifically within genes involved in cell growth and regulation can alter the sequences of their protein products and thus affect their function.

Inherited CRC syndromes initiate as a result of an inherited mutation in one of the genes involved in the CIN or MSI pathway. Although several CRC syndromes exist, the two most common are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC).[170,286] Most interestingly, tumors in FAP kindreds and tumors displaying CIN more frequently are found in the distal part of the colon, whereas tumors in HNPCC families and tumors displaying MSI more commonly occur in the proximal part of the colon.[277]

FAP, characterized by hundreds to thousands of adenomatous polyps throughout the large bowel, is inherited in an autosomal dominant fashion. Penetrance is 80% to 100%, and the estimated incidence is 1 in 8000.[66] FAP accounts for less than 1% of CRC observed in the United States. In about 25% of cases no family history exists, indicating that these cases arise as a result of a new mutation; there is no tendency for paternal versus maternal origin of the mutated allele.[66,482] Polyps first appear during the second decade of life.[452] CRC ultimately develops approximately 10 to 15 years after the onset of polyposis, with the median age of CRC in untreated FAP patients being about 40.[66,452] Although an individual polyp is no more likely to progress to cancer than a sporadic polyp, it is the sheer number of polyps in these patients that increases the likelihood that one will progress to cancer. Further, patients with FAP are at increased risk for developing cancer of the thyroid, small intestine, stomach, and brain.[170] The gene responsible for FAP, the *APC* gene, was ultimately cloned in 1991 following linkage to chromosome 5q21 (long arm of chromosome band 21) in FAP kindreds in 1987.[68,219,302,409,423] The *APC* gene spans 8535 base pairs, contains 15 exons, and encodes a protein of 2843 amino acids with a molecular weight of about 312 kD. The APC protein is a multidomain, multifunctional protein, partici-

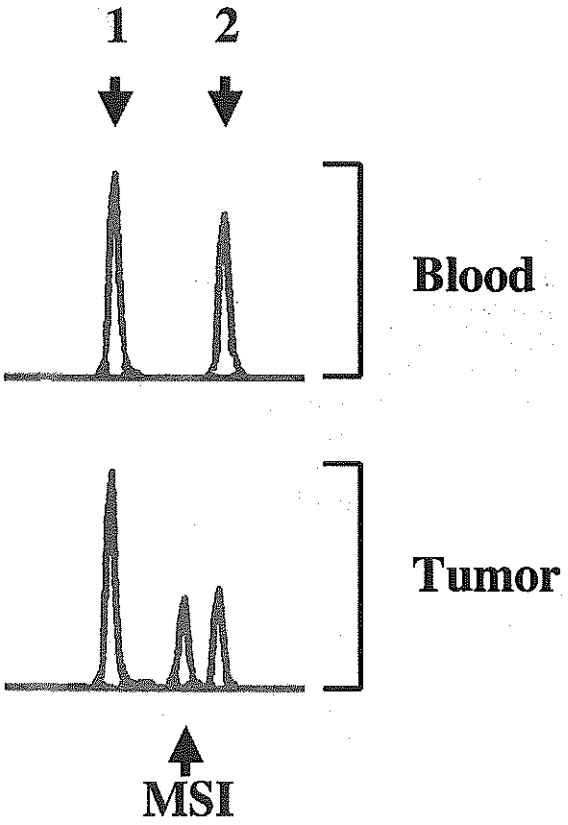

Figure 40-12 Electropherograms illustrating MSI in tumor DNA. Patient DNA is extracted from the peripheral blood and tumor tissue and amplified by PCR using an oligonucleotide primer pair specific for a microsatellite repeat locus. One of the primers within the pair is labeled with a fluorescent dye. Amplicons are subjected to electrophoresis on a 5% denaturing polyacrylamide gel in an ABI DNA sequencer and analyzed by GeneScan software 3.1 b3. Constitutive DNA from the patient's blood illustrates heterozygosity for this marker with amplicons represented by alleles 1 and 2. In DNA from the tumor, in addition to constitutive alleles 1 and 2, amplicons representing DNA fragments of a different size are present; these indicate a change in repeat number for one of the alleles. Because of dysfunctional MMR enzymes, mistakes occurring during the replication of microsatellite repeat sequences resulting in expansions or contractions of the repeat number remain unrepaired. In this case, a contraction in the repeat number of allele 2 has occurred. (See Color Plate 11.)

pating in several cellular processes, including cell adhesion and migration, signal transduction, microtubule assembly, and chromosome segregation. Best understood is the regulation of β-catenin levels through interaction with APC. β-catenin is required for binding with E-cadherin, a member of the calcium-dependent cell adhesion molecules, and is also involved in signal transduction pathways.[63,182] Mutations altering the association of β-catenin with APC minimize degradation and increase cytoplasmic levels of β-catenin; this can affect cell-cell adhesion and the transcription of genes, promoting cell proliferation (specifically *CMYC*) or inhibition of cell death.[245,395]

Studies on FAP families indicate that a wide variety of germline mutations exist; >95% result in truncated proteins, either because of a nonsense mutation (30%) or by a frameshift mutation, and most are contained within the 5′-half of the gene.[56] In germline mutations there are two hot spots at codons 1061 and 1309, with the most common mutation being an AAAAG deletion at codon 1309. These mutations leave the truncated APC protein unable to regulate β-catenin.

Genotype-phenotype correlations exist for some *APC* mutations. Patients with truncating mutations at the extreme 5′-end of the gene (codons 1 to 163) or mutations at the carboxyl-terminal end of the gene (codons 1860 to 1987) have the attenuated form of the disease, developing a smaller number of polyps (<100).* A severe phenotype is observed in patients with mutations between codons 1250 and 1464, and patients with truncating mutations between codons 1403 and 1578 are at an increased risk for extracolonic disease.[145,404] Intrafamilial and interfamilial phenotypic variability exists even in the presence of an identical mutation and may be explained by a modifier gene or genes.[122,199] The site of the inherited germline mutation appears to influence the type of somatic inactivating mutation occurring at their normal *APC* gene.[322] If the germline mutation occurs between codons 1194 and 1392, the second hit to the normal allele is likely a deletion encompassing the *APC* allele. However, if the germline mutation is outside this region, the second hit will likely result in a truncating mutation within the mutation cluster region (MCR) between codons 1286 and 1513.[322,382]

The PTT is most often used to test for mutations in a family because the majority of FAP mutations result in a truncated protein. Once a possible mutation has been detected, the region is sequenced to determine the precise identity of the mutation.[204,460] Other screening or direct detection methodologies can be used, and collectively a sensitivity of about 87% can be achieved.[359,429] If the mutation within the family can be identified, it is recommended that the family be referred for genetic counseling. DNA testing should be performed in at-risk family members as young as 10 to 12 years of age.[198] Genetic testing can significantly alter the 50% pretest risk for disease to a risk of 0% or 100%. Although DNA testing on an asymptomatic minor is typically not endorsed by the genetic community, in this scenario, early identification of the mutation in these patients will clearly impact their clinical management by initiating intense screening programs and possible prophylactic colectomy in that decade. Family members testing negative for the mutation do not have an increased risk of CRC and can avoid intensive screening programs. Further, in some FAP mutation–positive families, preimplantation genetic diagnosis has been successfully employed to prevent the birth of a child with an inherited predisposition to FAP.[473]

*References 80, 169, 187, 530, 542, 593, 618.

If the mutation in the family cannot be identified, DNA linkage studies may be useful for presymptomatic identification of at-risk family members. If the mutation in the family cannot be identified and if DNA linkage studies are not informative or available, screening is recommended with yearly sigmoidoscopy as early as age 12. Further, when repeatedly negative sigmoidoscopy results are found, the frequency of such exams can be reduced in each subsequent decade of life.

The most common inherited CRC susceptibility syndrome is HNPCC, which represents about 2% to 3% of all CRC cases. In contrast to FAP, HNPCC is characterized by a few polyps that possess an accelerated transformation potential to carcinoma in as little as 1 to 2 years. HNPCC is inherited as an autosomal dominant disorder with a penetrance of 80% to 85%. HNPCC is sometimes also referred to as Lynch syndrome for Dr. Lynch's observation of an autosomal dominant predisposition to early onset CRC of proximal involvement and cancers of other organs in two large Midwestern kindreds.[350] HNPCC patients have a lifetime risk of 70% to 80% for developing CRC, thereby suggesting a role for other factors in this disease process.[224] To assist clinicians in identifying patients in HNPCC kindreds and to help standardize the ascertainment and study of these families, the International Collaborative Group on HNPCC developed the Amsterdam criteria (AC) in 1991.[597] Basically the criteria for inclusion as an HNPCC family included at least three affected members spanning two successive generations with the diagnosis of colon cancer before the age of 50. In addition, one affected individual must be a first-degree relative of two other individuals, and because this mode of inheritance is consistent with autosomal dominant, the diagnosis of FAP must be excluded. Because some HNPCC families were excluded by these stringent criteria, and these criteria did not account for the risk to these patients for cancers of other organs as well, an expanded, more inclusive set of criteria was subsequently developed in Bethesda in 1998 and as the Amsterdam criteria II in 1999.[71,598] The expanded definition would also include a kindred with multiple family members affected with HNPCC-associated cancers of the endometrium, ovary, stomach, hepatobiliary system, small bowel, ureter, or renal pelvis with a diagnosis before age 45 and demonstrating autosomal dominant transmission between two generations. In addition, if an individual has endometrial cancer or CRC before age 45 (which is about 30 years earlier than that seen in the general population) or a colorectal adenoma diagnosed before 40 years of age, or if an individual has two HNPCC-related cancers, including synchronous and metachronous CRC or associated extracolonic cancer, the patient could meet the criteria as a possible HNPCC patient.

Mutations in six mismatch repair genes have now been linked to HNPCC. The first was mapped to 2p15-16 using large HNPCC kindreds.[447] Simultaneously, MSI was noted in a subset of sporadic CRC.[281,569] Concurrently in yeast genetics, Strand et al reported that mutations in three yeast genes involved in DNA MMR led to 100-fold to 700-fold increases in mutations in simple repetitive sequences and postulated that the human homologues of these genes may be involved in HNPCC.[546] One such gene, *hMSH2,* mapped to 2p15-16 and in fact was found to be altered in HNPCC kindreds.[179,324] Subsequently, mutations in genes *hMSH6* (2p15-16), *hMLH1* (3p21), *hPMS1* (2q31), *hPMS2* (7p22), and *hMLH3* (14q24.3) have been identified in HNPCC families, although more than 90% of HNPCC mutations are observed in *hMSH2* and *hMLH1.*[82,380,421,640]

HNPCC mutations are diverse and are located throughout these genes.[448] Almost all errors made during DNA replication are repaired through the proofreading 3′-to-5′ exonuclease activity of DNA polymerase. Uncorrected errors of mismatched bases between the two strands are repaired before cell division through the MMR proteins.[292] In addition to the repair of a mismatched base pair, the MMR system repairs "loop outs" from unmatched bases that can occur during the replication of a microsatellite or small repetitive sequences. In the case of HNPCC, a germline mutation in one of the six known MMR genes is inherited, causing one allele to be nonfunctional. In the tumor tissue of these patients, the second allele has been rendered inactive through a second mutational hit. Uncorrected somatic replication errors thus accumulate both within noncoding and insignificant locations throughout the genome and in coding regions of genes involved in cell growth and signaling and in DNA of other genes involved in DNA repair. Some targeted genes with repetitive sequences in their coding regions that have been shown to be altered in patients with MSI include transforming growth factor B type II receptor (tumor suppressor), insulin-like growth factor II receptor (tumor suppressor), *BAX* (promotes apoptosis), and *hMSH6* and *hMSH3.*[8,446,469,541]

MSI is identified in 90% of HNPCC-related CRC as opposed to only 15% to 20% of sporadic CRC.[1] MSI in sporadic CRC is attributed to inactivation of gene expression of *hMLH1* through biallelic methylation rather than as somatic mutations or loss of heterozygosity (LOH) as seen in HNPCC-related CRC.[313,601] Further, patients whose tumors demonstrate MSI have better survival and better response to chemotherapy than those whose tumors do not express MSI.[159,233] No association between tumor MSI and survival was seen, however, in young patients under the age of 30.[166]

Testing of tumor tissue for MSI (see Figure 40-12) is the initial laboratory step in investigation of HNPCC patients because MSI is a measure of MMR deficiency and indicates probable defects in MMR genes through germline and somatic changes. International guidelines for analysis of MSI in CRC recommend a panel of five markers: BAT25, BAT26, D5S346, D2S123, and D17S250.[71] MSI is characterized by the expansion or contraction of DNA sequences through the insertion or deletion of repeated sequences. If MSI is detected at two or more of the five loci, the tumor has a "high" frequency of MSI. If MSI is detected at one locus, the

tumor has a "low" frequency of MSI. If MSI is not detected at any locus, the tumor is considered to be microsatellite stable.

If the family history supports the diagnosis of HNPCC and if MSI is confirmed in the tumor, DNA from the patient's blood can be referred for testing to identify the germline mutation that could be segregating in the family. Since most mutations occur in genes *MLH1* or *MSH2,* DNA sequence analysis of these genes is most often used and is considered the gold standard but is expensive. Since many mutations result in prematurely truncated proteins, PTT is sometimes used as an initial screening tool. However, optimal mutation detection in HNPCC can be achieved only by combining expert clinical selection of families with an extensive strategy to detect mutations.[613]

If a mutation is identified, at-risk adult family members could pursue presymptomatic testing if desired and if appropriate genetic counseling is supplied.[96] Similar to presymptomatic testing for other adult-onset disorders, the counseling session should include verification of the family history and discussion of the clinical course of the disease, including risks of developing the disease and issues in disease management. Discussions should be incorporated into the session, including how the patient will act upon both positive and negative results, feelings of survivor guilt or stigmatization, and the possibility of discrimination for insurance and employment. If a germline mutation is detected, a colonoscopy should be performed every 1 or 2 years or 5 years younger than the youngest age of diagnosis in the family.[411] Further, because of the high incidence of endometrial cancer associated with HNPCC, at-risk women in the family should be screened for endometrial cancer annually with endometrial aspiration biopsy and transvaginal ultrasound beginning at age 25.[91] Alternatively, if genetic testing is not pursued, relatives should begin an intensive screening program with a colonoscopy every 1 to 2 years starting between 20 and 30 years of age and then annually after age 40. If no mutation is detected in the proband, presymptomatic DNA testing for family members is not recommended. Some testing strategies may result in false-negative results caused by the inability of the assays employed to identify all mutations at these loci. However, some mutation-negative families may have germline mutations in other, yet unknown MMR genes.[289] Although detection of a mutation in a family that meets HNPCC criteria is not always possible, careful surveillance of at-risk family members in mutation-negative families is also considered critical.

REPORTING OF TEST RESULTS

As the preceding pages make clear, DNA testing for inherited diseases is complex, and it is most important to convey the results of a genetic test thoroughly. Results must be presented in a manner that can be easily and accurately understood by a professional whose expertise is not genetics because, in many instances, primary care givers will be communicating the test results to the patient. Unfortunately, however, with the increasing clinical demand for genetic testing and the increasing number of laboratories performing such tests, uniformity in communicating these complex results to referring clinicians does not exist.[17] The Molecular Pathology Laboratory Inspection Checklist of the College of American Pathologists (CAP) indicates that failure to include pertinent information within the patient report constitutes a deficiency.[507]

Based upon the CAP guidelines, a comprehensive genetic report should include the patient's name; medical record number and/or birth date; sex; ethnicity (if relevant); type of specimen and date received; specimen's laboratory identification number; laboratory test requested; name and address of laboratory performing the test; name and address of referring physician, hospital, or genetic counselor; date of report; brief interpretation of the results; and a descriptive comments section explaining the test results. Although preparation of the comments can be labor intensive, the comment section is vital to a genetic report and should include the following: (1) brief clinical history of patient (indicating the reason for referral); (2) detailed explanation of the methodology (citing literature if possible); (3) description of the patient's results; (4) sensitivity and specificity of the assay (e.g., number of mutations analyzed, percentage of mutations not detected, possibility of genetic heterogeneity, and chance of genetic recombination); (5) clinical significance of the results (e.g., recurrence risk, genotype-phenotype correlation or penetrance, with citations of literature if possible); and (6) statement that genetic counseling for the patient is recommended to discuss the implications of the results for the health and management of the patient and, when mutations are identified, to inform the patient of the potential risk of the disease to other family members.

Because many assays performed in clinical DNA laboratories have been developed by the laboratory or use commercially available "analyte specific reagents" (ASR) that are not approved by the U.S. Food and Drug Administration (FDA), reports in the United States often must include a disclaimer that states, "This test was developed and its performance characteristics determined by (laboratory name). It has not been cleared or approved by the U.S. Food and Drug Administration."[215] In addition, the CAP recommends the additional statements: "The FDA has determined that such clearance or approval is not necessary. This test is used for clinical purposes. It should not be regarded as investigational or for research. This laboratory is certified under the Clinical Laboratory Improvement Amendments of 1988 (CLIA-88) as qualified to perform high complexity clinical laboratory testing."[507] Lastly the report should be reviewed and signed by the laboratory director.

GLOSSARY

Allele—An alternative form of a gene found at a specific location on a chromosome.

Crossover—See "Recombination."

Diploid—Having a full set of (paired) chromosomes (46 chromosomes in humans, half from each parent).

DNA marker—A polymorphic locus that is easily assayed, yielding reproducible results.

DNA methylation—The addition of a methyl residue to the 5 position of the pyrimidine ring of a cytosine base to form 5-methylcytosine and most often occurring at CpG DNA sequences. DNA methylation can serve as a mode of gene regulation by preventing gene transcription.

Downstream—A DNA sequence located 3′ to another DNA sequence.

Gene deletion—A circumstance in which all or part of a gene is lost.

Gene dosage—The number of copies of a particular gene. In most cases, there are two copies of each gene, thereby producing a fixed amount of the protein product from that gene. In situations in which more or fewer copies of the gene are present, ultimately, an increase or decrease in the protein product occurs.

Gene duplication—A condition in which all or part of a gene is repeated.

Gene inversion—A rearrangement of the gene or part of the gene causing the orientation of the DNA sequences in the gene to be reversed in relation to the flanking chromosomal DNA sequences.

Haploid—Having a single set of chromosomes, as in gametes (eggs and sperm) (i.e., half the number of chromosomes in a mature somatic cell).

Linkage disequilibrium—The occurrence of two alleles from two loci inherited together on a chromosome more frequently than predicted by chance.

Linkage studies—A method using DNA markers physically adjacent to (i.e., "linked") to a disease gene. Through this "indirect" analysis, the disease gene can be tracked through a family to determine the disease status of at-risk individuals without requiring knowledge of the diseasing-causing mutation segregating in the family.

Meiosis—The two-step process of cell division that produces gametes (ova in females and sperm in males) with one half the number of chromosomes of the parent cell. Contrast with mitosis.

Mitosis—Process of cell division that produces daughter cells that are genetically identical to the parent cell with the same number of chromosomes as the parent cell. Contrast with meiosis.

Haploinsufficiency—In the presence of a loss-of-function DNA mutation, the remaining normal allele is unable to produce sufficient quantities of the specific gene's protein product, and disease results.

Homologous sequences—DNA sequences that share a similar order of DNA bases. If two sequences are 95% homologous, 95% of their bases are identical at a particular location.

Microsatellite repeat markers—Highly polymorphic DNA sequences of short repeats generally comprising <6 bases. These repeats are widely prevalent in both coding and noncoding regions of the human genome.

Nondisjunction—Failure of chromosomes to separate during cell division.

Penetrance—The percentage of individuals who carry the disease genotype and have symptoms of the disease. Complete penetrance implies that all individuals who possess the abnormal allele will develop the disease, whereas incomplete or reduced penetrance indicates that not all individuals who have the disease allele will become symptomatic. Incomplete penetrance of a disease suggests that other genetic loci and/or environmental factors can influence or modify the pathogenesis of the disease.

Primer—A short oligonucleotide designed to anneal to single-stranded DNA and from which DNA polymerase can add deoxynucleotide triphosphate (dNTPs) in a complementary fashion to the template DNA. A primer pair flanks the target DNA to be amplified in PCR and creates the specificity of the reaction.

Recombination—Crossing over between DNA sequences resulting in the exchange of information between two alleles. This process occurs in meiosis between homologous chromosomes and during mitosis between sister chromatids. Homologous recombination refers to this process when it occurs between similar sequences in corresponding regions. Crossing over between misaligned yet similar sequences is called unequal homologous recombination and results in a duplication on one allele and the reciprocal deletion on the alternate allele.

Restriction fragment length polymorphism—A polymorphism in the DNA sequence that either creates or destroys a restriction endonuclease recognition site thereby enabling detection by altering base-pair lengths of digested DNA fragments.

Skewed X-inactivation (lyonization)—A process by which inactivation of the X chromosome is not random.

CHAPTER 41

Identity Assessment

Thomas M. Williams, M.D.,
Victor W. Weedn, M.D., J.D.,
and Malek Kamoun, M.D., Ph.D.

Identity testing exploits variations present within the human genome to distinguish between two individuals. Identity assessment has five basic uses: (1) confirm or refute that a sample is from a specific person in forensic testing; (2) resolve questions regarding the identity of a clinical specimen; (3) select donors for a planned transplant recipient to minimize rejection and improve graft survival, via histocompatibility testing; (4) assess whether hematopoietic cells are donor- or recipient-derived following stem cell transplantation; (5) identify the parents of a child.

VARIATION IN THE HUMAN GENOME

Identity testing began with the use of serological methods to identify variations in proteins that differ among individuals. The discovery of the genetic basis for these protein differences and of genetic variability at loci not encoding proteins, coupled with technical advances, allowed the field to move to direct analysis of DNA. Genetic variation among individuals is extensive, with about 1 sequence difference for every 400 to 1000 nucleotides on autosomal chromosomes. Variants of a genetic locus in a population are referred to as alleles. A locus is said to be polymorphic when the least common allele has a frequency of ≥0.01 in a population. While several alleles may be found in a population for an autosomal locus, an individual may have at most two alleles at that locus. There are several classes of genetic variants in the genome; some are more useful than others for identity testing.

Genetic Variation Useful in Identity Testing

Highly repetitive sequence elements that contribute to the structure of centromeres and telomeres and hundreds of thousands of copies of transposable elements that move about the genome over time may vary among individuals. However, these repetitive sequence elements are generally not useful for identity testing. More than 1 million single nucleotide polymorphisms (SNPs) have been identified in the genome. A subset of SNPs can be identified based on the ability of a restriction endonuclease to digest double-stranded DNA at the site of the variation. These SNPs are referred to as restriction fragment length polymorphisms (RFLPs). SNPs and RFLPs have been important in genetic linkage analysis and the study of disease pathogenesis; however, they are less useful for identity testing because they usually have only two alleles.

Variable numbers of tandem repeat loci (VNTRs) or minisatellite loci consist of repeated sequences of DNA. The number of repeats varies from allele to allele. This difference can be detected as an RFLP if the locus containing the VNTR is digested with a restriction endonuclease and hybridized to a labeled DNA probe in Southern hybridization assays. VNTRs are attractive for identity testing, because the loci usually have a number of different alleles with relatively high allele frequencies. Minisatellite regions are commonly subtelomeric and have core repeats of 8- to 80-base pair lengths, resulting in DNA fragment lengths of 0.5 to >20 kilobases.

Short tandem repeat (STR) or microsatellite loci consist of DNA sequence motifs that have core repeats of two to seven base pairs.[5,13] Examples include the dinucleotide 5′ CACACACA 3′ and the tetranucleotide 5′ TTTATTTATTTA 3′. Thousands of STRs are scattered throughout the genome. Because they are flanked by unique sequences, each can be specifically amplified with the polymerase chain reaction (PCR) for analysis. In populations of individuals, multiple alleles may be present based on differences in the number of repeated motifs at the locus. STRs have many characteristics that make them ideal for identity testing: (1) They can be analyzed in fluorescent automated systems; (2) alleles can be assigned in a definitive manner following analysis; (3) STR loci are almost always transmitted in families in a Mendelian fashion; (4) the loci may have 10 or more alleles, often with

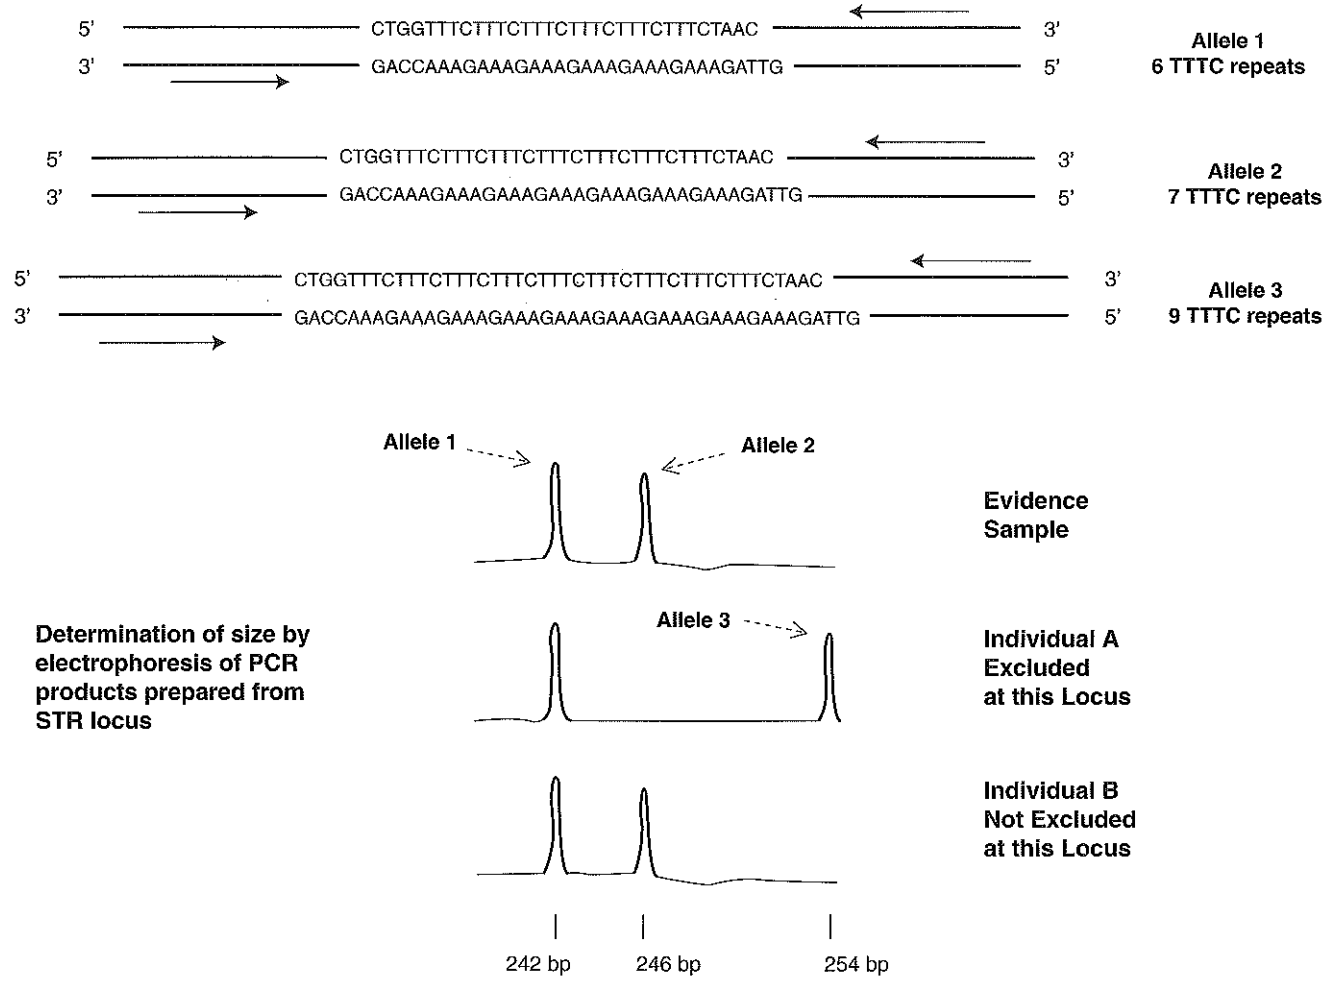

Figure 41-1 Identity testing via STR analysis. A STR locus can be specifically amplified with the PCR using primers binding to unique sequences adjacent to the repeat motif in the genome. In the example shown, the polymorphic repeat is the tetramer TTTC. Three example alleles with 6, 7, and 9 repeats at this locus are shown. The genotype for an individual or evidence sample can be determined by performing the PCR with a fluorescently labeled primer and sizing the products on a high-resolution gel with laser detection. The PCR products should differ in size from each other by multiples of 4 nt. The use of several fluorescent dyes and different-sized PCR products allows multiplexing for assessment of a number of independently segregating STR loci simultaneously.

substantial allele frequencies, making them highly informative; and (5) extensive information is available about allele frequencies in many human populations for STRs commonly used in identity testing.[6]

Commercially available STR systems employ tetrameric and pentameric repeat loci, which produce fewer artifactual bands and are characterized by roughly equal amplification of both alleles in an individual (Figure 41-1). Fragments can be labeled during the PCR amplification with fluorescently tagged primers that facilitate multiplexing.

Two special genetic regions with sufficient sequence variability for identity testing include the human leukocyte antigen (HLA) loci within the major histocompatibility complex (MHC) and the mitochondrial DNA. The HLA loci described in the Transplantation Testing section later in this chapter are interesting in that the polymorphisms are densely packed and preferentially located in the exons rather than the introns of these genes on chromosome 6. Mitochondrial genome variation is useful in forensic identity testing and is described in that section.

Exclusion of Tested Individuals

The exclusion of a tested person in identity testing is based on the presence of alleles at a locus that make it impossible for him or her to be a contributor to the tested sample. For example, if the person has the alleles j and k at the autosomal locus L, then, in the absence of mutations, it is not possible for him to be the major contributor to an evidence sample with the alleles m and n at L or to be the father of a child with the alleles m and p at L. In practice, laboratory

protocols require that exclusion be based on incompatible results for at least two loci to rule out mutation events or other sources of error. In this context, "impossible" implies a situation in which samples have been collected correctly and have not been mislabeled, testing has been performed accurately, and results have been interpreted and reported appropriately.

Likelihood of Inclusion of Tested Individuals

If a tested individual has genotypes at several loci that are identical to the genotypes found in an evidence sample, then that person is not excluded as the contributor to the sample. The inclusion of a tested individual in identity testing is based on a probability calculation relying upon knowledge of the allele frequencies in human populations for the tested loci. For each locus, the likelihood that a random person of relevant ethnicity would have a genotype identical to that found in the evidence sample can be calculated. If the tested loci independently segregate during meiosis, the overall probability that a random person rather than the accused is responsible can be calculated by multiplying the likelihoods for each locus. When several loci are tested and each has many possible alleles, it becomes extremely likely that an individual whose genotypes match those found in the evidence sample is the person who contributed the DNA to the sample.

Discriminatory power is the ability of an identity testing system to distinguish an individual or group from the rest of the population. The power of discrimination of a locus or testing system should not be confused with accuracy. ABO blood group typing is accurate, but poorly discriminating, since this locus results in only a few phenotypes of generally high frequency in populations. Current identity test systems that employ a number of highly polymorphic loci may have powers of discrimination that exceed 1×10^{-10}, making it very unlikely that any unrelated individual on earth other than a nonexcluded suspect could be the source of an evidence sample. However, likelihoods of this magnitude should be viewed with knowledge that a variety of potential problems extraneous to the testing technology, involving sample collection and labeling, and test interpretation and reporting, may lead to an erroneous result.

Parentage calculations are often performed using Bayesian methods that consider the prior probability that an individual is the father of a child. It is obvious, for example, that the prior probability of a man living in Boston being the father of a co-worker's child is much greater than that of a Beijing inhabitant with no overt connection to the mother. Most crime laboratories in the United States do not report calculations using Bayesian analyses, but instead report the population phenotypic frequencies for White, Black, and Hispanic populations and sometimes a likelihood ratio that an individual is the source of a DNA specimen. When questions arise regarding assumptions that must be made during the calculation of inclusion probabilities, laboratories generally choose the conservative option that favors the accused individual.

Samples Employed for Identity Testing

Samples for identity testing can be any specimen that contains DNA. Samples obtained from an individual for paternity testing or as a reference sample to be compared with DNA prepared from evidence are usually peripheral blood or buccal mucosa. Samples useful for forensic testing, engraftment assays, and the identification of clinical samples may range from plucked hairs to bone marrow aspirates to paraffin embedded tissue. While subject to degradation over time in the presence of enzymes, acidic or basic conditions, or high temperature, DNA is a remarkably stable molecule that can be recovered and successfully analyzed from solutions, surfaces, and cells.

FORENSIC DNA TYPING

DNA testing has revolutionized criminalistics.[15,29] Only fingerprint evidence can rival the ability of DNA as trace evidence left at a scene to identify a perpetrator. As a general rule, other trace evidence merely links an article, instrument, or material to a scene. The origin of DNA-based identity testing is generally traced to a 1985 article in *Nature* by Alec Jeffreys.[14] He coined the term "DNA fingerprint" and suggested that the hybridization of DNA probes to polymorphic genetic loci could be exploited for forensic purposes. Jeffreys first applied his techniques to civil and criminal cases in England. In the United States, DNA-based identity testing was introduced via commercial laboratories and later the Federal Bureau of Investigation (FBI). Today there are approximately 200 forensic DNA typing laboratories in the United States and many other DNA laboratories around the globe.

Forensic Applications

Forensic testing differs from clinical laboratory testing in several ways: (1) The forensic question is usually one of identity rather than one of presence or absence, character, or quantity as in most clinical laboratory analysis. (2) Specimens received by forensic laboratories are much more diverse than the typical blood, fluid, and tissue samples handled by clinical laboratories. (3) Clinical samples are collected under controlled circumstances, while evidence from which DNA must be isolated may be exposed to the environment in a variety of ways. Experiments may be necessary to validate testing for a particular case. (4) Evidentiary material cannot be replenished and may be present in only trace amounts. Testing may consume the sample and thus complete or repeat testing may be impossible. (5) Forensic identity testing is scrutinized in a judicial environment requiring complete accounting for the whereabouts of evidence following its collection and strict validation of procedures. Most other laboratorians perform routine analyses of samples collected in defined ways. Forensic identity testing must contend with much more variability in samples and testing conditions.

TABLE 41-1 DNA Typing Systems and Their Characteristics

Genetic Systems	Timeframe	PCR-based	Discrimination	Comments
RFLP analysis of VNTRs	1980s-1990s	–	++++	Labor intensive
PCR dot-blots	1980s-1990s	+	+	Limited discrimination
STRs	Late 1990s to present	+	++++	Current mainstay
mtDNA	Mid1990s to present	+	++	Used in hairs, skeletons
Y-markers	Beginning use	+	++	Male DNA
Alu repeats	Not yet in use	+	++	Population marker
SNPs	Not yet in use	+	+++	Useful for samples with highly degraded DNA

Genetic Systems Used in Forensic Identification

Numerous genetic systems that are employed by forensic laboratories are summarized in Table 41-1.[3,21]

VNTR Analysis by RFLP

Jeffreys described a method to create a barcode-like DNA fingerprint based upon VNTRs. Because the probes used bind to several loci in Southern hybridization experiments and produce numerous bands per probe, they are termed "multilocus probes." In the United States, laboratories prefer single locus probe (SLP) systems that hybridize to only a single genetic locus. SLPs generally yield one or two bands on an autoradiogram per probe. SLP genetic systems are robust and generate readily interpretable bands, more precise allele frequency statistics, and less sensitivity to fragmentation of high molecular weight DNA.

RFLP testing with SLPs was the predominant method of DNA typing in most forensic laboratories throughout most of the 1990s. RFLP testing commonly employed six genetic loci: D1S7, D2S44, D4S139, D10S28, D14S13, D17S79. The resulting average discrimination for Caucasian Americans is approximately 1 in 1.2×10^{11}. However, Southern hybridization–based RFLP analysis is expensive, labor intensive, difficult to automate, and less sensitive than PCR-based methods. Furthermore, RFLP tests suffer from allele sizing imprecision, requiring that the results be binned and statistical measures of confidence employed for interpretation. Finally, RFLP is sensitive to DNA degradation—an important issue with environmentally exposed forensic specimens. RFLP tests have been largely abandoned in favor of the more efficient PCR-based assays discussed below.[4]

Short Tandem Repeats

Most identity testing performed today relies on the PCR. PCR testing is inherently sensitive, allowing routine analysis of nanogram quantities of genomic DNA and often successful testing of picogram quantities (one cell contains 5 to 10 pg of DNA). The PCR underlies the characterization of STR and other loci for forensic identity testing loci described in this and later sections below.

STR testing is quick, less expensive, more forgiving with respect to technical skills needed, less sensitive to DNA degradation, and more amenable to automation in comparison with the Southern hybridization methods described above. Although less discriminating than RFLP genetic markers, STR analysis can be made as powerful as Southern RFLP analysis through the use of large numbers of informative loci.

The National Institute of Justice provided funding for the initial application of STRs in forensics. STRs were used in forensic casework during the first Persian Gulf War and were widely adopted for testing by forensic laboratories in the United Kingdom and the United States in the mid to late 1990s.

The FBI convened a panel of forensic scientists in 1998 that chose a panel of 13 STR loci for use in the National DNA Index System. These "13 core loci" have become the standard for casework and databanking for most forensic laboratories around the world (Table 41-2). They have been commercialized as kits by Promega (Madison, Wis.) and Applied Biosystems (Foster City, Calif.; a division of PerkinElmer) in a variety of formats. STRs are now routinely used in crime labs globally and typically yield discriminatory values of one in trillions to quadrillions.

Gender Markers and Y-Chromosome Markers

The amelogenin locus is useful as a gender marker. The X chromosome amelogenin gene differs from its homologue on chromosome Y by a six base pair polymorphism, allowing the distinction between individuals with 46,XY and 46,XX karyotypes. Males will display amelogenin locus heterozygosity; females will exhibit homozygosity. Reagents for assessing the amelogenin locus are incorporated in commercially available STR kits.

Y-chromosome polymorphic loci can be used as identifying loci found only in males. In this way, the male-specific DNA obtained from a vaginal swab can be typed without the usual "differential extraction" in which the DNA from

Y-chromosome markers are listed in their major haplotype groups.

spermatozoa is released after the female fraction from epithelial cells. Y-chromosome loci useful for identity testing include STRs or SNPs (described later in this chapter). Laboratories typically employ locally developed or commercially available panels of 6-20 Y-chromosome STRs for analyses (Table 41-3). Y-chromosome SNPs are in development.

Y-chromosome polymorphic loci are linked, resulting in discriminatory power significantly less than a panel of independently segregating somatic STR loci. Discriminatory values can be increased by using a large panel of Y-chromosome markers in conjunction with a large database of typed individuals.

Mitochondrial DNA

Mitochondrial genomes are circular double-stranded DNA molecules, which are 16,569 base pairs long, that are present as one or more copies within the mitochondria of a cell. Thus mitochondrial DNA (mtDNA) is present in hundreds to thousands of copies per cell. MtDNA, unlike chromosomal DNA, does not undergo meiosis and does not participate in genetic recombination events. MtDNA remains stable over generations, except for the acquisition of mutations at a rate 10 to 20 times that of nuclear DNA.

MtDNA is transmitted to children via oocytes. Although it is generally thought that mitochondrial DNA is exclusively derived from the mother, a minor contribution from the father is occasionally present, particularly in disease states. The normal state of mitochondria is generally thought to be one of "homoplasmy," in which all the mtDNA has the same sequence. However, because of mutational events, a state of "heteroplasmy" in which more than one mtDNA sequence is present in the same tissue may exist. High-level heteroplasmy is generally of the order of 30% of the mtDNA sequence before it is reported. Unrecognized low-level heteroplasmy is common. Heteroplasmy appears to be somewhat tissue-specific rather than uniform throughout the body. Thus two shed hairs may show discrepant mtDNA sequences. Due to heteroplasmy, one or two nucleotide mismatches between two individuals is not an absolute basis for exclusion of a tested individual.

In the human mitochondrial genome, only approximately 1200 bases in the region of transcription origin (15971-579), known as the "displacement loop" (D-loop) or "control region," are noncoding. This D-loop contains two hypervariable regions that contain the majority of polymorphisms useful for identity (HVI: 16024-16365, HVII: 73-340). Polymorphisms outside this region can also be employed for testing. MtDNA polymorphisms are typically identified for forensic testing via DNA sequencing of the hypervariable regions.[13] This method is expensive, labor intensive, and highly sensitive to contamination. A limited number of laboratories offer this service. More convenient hybridization technology for mtDNA testing has recently been introduced as a "linear array" by Roche Molecular Systems (Alameda, Calif.).

The mtDNA sequence obtained from a specimen is compared with the "revised Cambridge" reference sequence. Because mtDNA polymorphisms are linked, the individual polymorphism frequencies cannot be multiplied together to generate a likelihood of identity like independently segregating chromosomal locus allele frequencies. Instead the mtDNA haplotype identified in a sample is compared with those deposited in a database to derive a frequency statistic. Most mitochondrial haplotypes in the database are unique. Since the database has greater than 600 entries, it can be fairly stated that most mitochondrial haplotypes have a discriminatory value of greater than 1 in 600. However, there are 18 common haplotypes with population frequencies greater than 0.5% including a haplotype present in 7% of the population. In aggregate, these common haplotypes account for 20% of all haplotypes.

MtDNA is primarily useful in identity testing in three contexts. First, a sample may be available that contains mitochondrial but not nuclear DNA. For example, shed hairs that do not have roots generally contain only mtDNA. Second, when the DNA within a specimen, such as skeletal remains, is substantially degraded, the high copy number of mtDNA makes it more likely to yield a result than nuclear DNA. Third, mtDNA analysis may become essential when only a distant relative is available for a reference specimen. In this example, nuclear DNA requires samples from multiple close kindred, but mtDNA matching would require only a distant maternal relative.

Single Nucleotide Polymorphisms

A DNA locus whose polymorphism extends over a short region is generally preferable for identity testing, because it may remain intact and available for analysis in the face of extensive levels of DNA degradation. Loci for which a single base pair varies in a population of individuals are referred to as SNPs. These are the most common type of polymorphisms in the human genome. They are particularly amenable to automation and chip technology using hybridization, polymerase extension, or ligation reaction assays. Despite a four-base possibility, most are biallelic with a dominant and nondominant allele. A large set of SNPs must be used to obtain significant discriminatory values. SNPs are not used in forensic laboratories at this time, but are likely to be used in the near future. SNP analysis is expected to be particularly useful in identifying individuals killed in the World Trade Center collapse for whom only severely degraded DNA samples are available.

Other Systems

Other systems are also being pursued for forensic identity testing, generally for phenotypic information. The Alu family of mobile elements comprises 5% of the human genome. These elements repeatedly insert themselves into the human genome. Polymorphisms occur within these elements so that the age of the element can be inferred. The systems are inherited; the recent polymorphisms become markers of descent and older elements (without the Alu insertion site) are markers of root ancestry. Similarly, the L1 family of long interspersed elements (LINES) can be used to trace evolutionary ancestry. In combination with other genetic systems, Alu and LINE markers will provide some statistical inference about human evolution and race and ethnicity that may be helpful to investigators.

Instrumentation Used in Forensic Laboratories

Most forensic DNA testing is performed using capillary electrophoretic (CE) systems. These systems have a substantially faster run times and higher resolution than slab gels. The ABI Prism 310 Genetic Analyzer is currently the most popular instrument for forensic DNA casework, but other CE systems are also available. Instrumentation allowing "on-demand" handling of a few specimens at fast run times is convenient for most casework. High-throughput capillary instruments are used as "batch" instruments for DNA databanking operations. The ABI Prism 3100 Genetic Analyzer is available as a 4 or 16 capillary system and the ABI Prism 3700 DNA Analyzer is a 96 capillary unit. Amersham Biosciences sells the Megabace series of instruments that can be configured with 48, 96, or 384 capillaries.

Instrumentation under development for forensic testing generally focuses on a goal of miniaturization yielding ultrafast and portable assays that would be useful for field testing. Network Biosystems (Boston) is miniaturizing capillary arrays by etching microchannels into large chips, resulting in an ultrafast CE array that has run times of seconds and produces sharper bands than conventional CE instruments. Nanogen (San Diego) has produced chip technology based on "electronic stringency control" that can detect STR and SNP systems.

Quality Assurance and Accreditation in Forensic DNA Analysis

Crime labs are unregulated, except in the case of submission of DNA results to the National DNA Index System (NDIS) through the Combined DNA Index System software. The

DNA Identification Act of 1994 gave the FBI regulatory oversight of DNA profiles entered into the national database. The legislation called for a DNA Advisory Board that produced recommended standards, based largely on guidelines of the FBI's Technical Working Group on DNA Analysis Methods (TWGDAM). The Scientific Working Group on DNA Analysis Methods, which has replaced the TWGDAM, now advises the FBI Director to create standards revisions.

One aspect of the FBI/DNA Advisory Board standards is a requirement for accreditation. The National Forensic Science Technology Center and the American Society of Crime Laboratory Directors/Laboratory Accreditation Board (ASCLD/LAB) accredit crime laboratories. ASCLD/LAB requirements include minimal educational credits and experience, proficiency testing twice a year per analyst, and annual audits. All testing requires a technical and an administrative review. An additional NDIS audit is required by the FBI. Judicial scrutiny provides another layer of critical review of those cases heard in court. Defense review and challenge, however, vary greatly.

Proficiency test providers for forensic laboratories include the Collaborative Testing Service, the College of American Pathologists, Cellmark Diagnostics, and Quality Forensics.

Standard reference materials from the National Institute of Standards and Technology (NIST) are available for RFLP Profiling (SRM 2390), PCR-based Profiling DNA standard (SRM 2391b), Y-chromosome testing (SRM 2395), and mtDNA testing. Standards require annual NIST-traceable comparisons.

Statistical Interpretation

In the early days of DNA-based identity testing, significant challenges were launched regarding the interpretation of DNA typing results.[7,11,16,30] Questions included whether loci exhibit Hardy-Weinberg equilibrium and whether allele frequencies vary significantly among ethnic groups. Current forensic genetic systems have not demonstrated significant deviation from Hardy-Weinberg equilibria. The systems also show greater intragroup allelic diversity than between-group diversity. A National Research Council panel was created to address these issues.[18] The resultant report (so-called "NRC I") introduced a "ceiling principle" to ensure the conservativism of the frequency estimates, which itself generated considerable controversy. This led to NRC II, which articulated the current standards of statistical analysis.[19] Statistical formulas are routinely applied to Caucasian, Black, and Hispanic population databases. Specialized databases also exist for Native American Indian and for Pacific and African populations.

Convicted Offender Databases

All 50 states now have convicted offender databases. Initially, most databases exclusively contained sexual offenders, but the recent trend is to expand the databases to include all felons. States have begun to consider collecting DNA evidence in connection with lesser crimes, such as burglaries, to help solve these cases, to potentially interdict the progression to more serious future offenses, and to identify "hits" in the databases linked to past serious crimes. Three states (Louisiana, Texas, and Virginia) have recently adopted legislation allowing collection of DNA specimens on arrest.

DNA profiles are placed in the NDIS. If a "hit" is determined, the local crime laboratories of the involved states are put in contact to discuss details. Identifying information other than the DNA profile is not entered into the system. Uploading of DNA profiles triggers quality assurance requirements and legal constraints on the use of the DNA specimens and profiles.

The use of identity testing and linked databases in crime investigation has been aggressively pursued in the United Kingdom. U.K. forensic scientists maintain that approximately 50% of biological specimens from crime scenes result in hits in their databases, suggesting that a relatively small group of professional criminals perpetrate most crimes. They believe that DNA-based testing may be a more efficient tool for investigating crimes than traditional methods, such as canvassing neighborhoods.

Legal Issues

Early challenges to the practice and interpretation of DNA-based forensic identification have faded as the public, attorneys, and judges have become more knowledgeable about this technology. The most common challenges today involve issues regarding sample collection, preservation of the evidence, chain-of-custody documentation, and validation studies. New applications of DNA-based testing to assess ethnicity or to infer phenotypic features from evidence or to identify an assailant from very small samples, such as fingerprints,[28] are likely to cause controversy in the future.

USE OF DNA TESTING FOR THE IDENTIFICATION OF CLINICAL SPECIMENS

Identity testing can also be used to confirm the identity of a clinical or anatomic pathology laboratory patient specimen.[24,25] Occasionally, questions arise regarding the identity of specimens in the clinical laboratory. DNA prepared from a peripheral blood or buccal mucosa specimen can be compared with the pathology specimen to confirm that it is derived from the patient. The authors have encountered a variety of requests for this specialized identity service. (1) A patient lost confidence that her breast biopsy results were hers following a series of reporting errors involving the spelling of her name and her birth date. (2) A biopsy of a colonic lesion revealed adenocarcinoma. The subsequent colectomy specimen was devoid of a tumor. (3) A gastrectomy was performed after a biopsy diagnosis of adenocarcinoma. No tumor was seen in the gastrectomy specimen. (4) Multiple blocks from two breast lumpectomy procedures were processed. Because of labeling errors, it was unclear

to which patient the various paraffin embedded blocks belonged. (5) A young male fractured his femur and developed osteomyelitis. Curettings from the fracture site demonstrated acute inflammation but also a fragment of tissue that appeared to be a squamous cell carcinoma.

In cases 1-4, identity testing with STRs demonstrated that all the specimens in question truly belonged to the involved patients. In case 5, testing following microdissection of the tissue fragments revealed that the squamous carcinoma "floater" was derived from another individual. The availability of identity testing in situations such as these can be a significant benefit to the involved patients and health providers.

In prenatal testing for inherited disorders, chorionic villus sampling (CVS) performed early in pregnancy is sometimes employed as a source of fetal DNA for testing. Testing for a disorder such as cystic fibrosis may reveal that the genotypes for the mother and the fetus are identical, for example that they are both heterozygous carriers of a cystic fibrosis mutation. This result is entirely consistent with the usual segregation of chromosomes during meiosis. However, there is a risk that the CVS material was not derived largely from the fetus but was decidual cells primarily from the mother. If the father is a carrier of a cystic fibrosis mutation, this may result in the failure to diagnose cystic fibrosis in a fetus. Identity testing can be employed to confirm that the tested cells have a genotype distinct from those of the mother and are a valid sample from the fetus.

TRANSPLANTATION TESTING

Obtaining well-matched tissue enhances transplanted organ and bone marrow survival. The human leukocyte antigen (HLA) alleles determine the tissue compatibility for the acceptance of transplanted allografts. HLA genes encode highly polymorphic cell surface molecules that are strong alloantigens. A kidney allograft is rejected as a result of an immune response directed against HLA alloantigens, which are expressed on the graft but are absent from the host.

GENETIC FEATURES OF HLA GENES

The HLA genes are located within a genetic complex designated as the MHC. The MHC includes about 4 Mb on the short arm of chromosome 6 (6p21.3). Many of the more than 200 genes in the MHC are involved in the regulation of the immune response.[16,20] The genes encoding the HLA class I (A, B, and C) and the class II (DR, DQ, and DP) molecules are the most polymorphic loci in the human genome (Figure 41-2 [Color Plate 12] and Table 41-4). This polymorphism made the HLA loci an attractive and powerful early resource for identity testing.

HLA genes are co-dominantly expressed and most individuals are heterozygous at the HLA class I and class II loci. Most of the sequence diversity for the HLA class I loci is located in the second and third exons and, for the class II loci, the second exon. These domains encode the peptide-binding regions of the HLA molecules. The pattern of allelic sequence diversity for both the class I and class II loci is unusual; most alleles differ from their closest neighbor by multiple substitutions, with some alleles differing in the second and third exons by as much as 15%. This pattern is suggestive of segmental exchange of nucleotide motifs between alleles of the same locus. As a result, different HLA alleles are mosaic-like combinations of a subset of all polymorphisms.[10,17]

Although a very large number of alleles (e.g., >400 for HLA-B and HLA-DRB1) can be found in the worldwide population, a much smaller number (e.g., 30 to 50 for HLA-DRB1) is present in most individual populations.

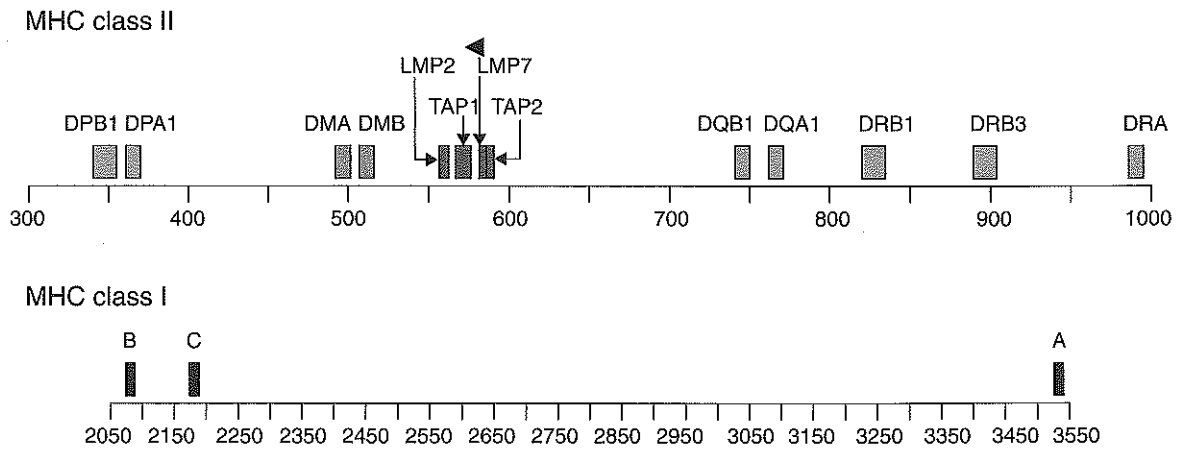

Figure 41-2 Map of the human MHC region. The organization of the most important class I and class II genes of the MHC is shown, with approximate genetic distances given in thousands of base pairs (kb). Genes are ordered from telomere to centromere. Not shown are MHC class III genes, which map between class I and class II genes. (See Color Plate 12.)

Importantly, different populations tend to have different frequency distributions of alleles and exhibit different patterns of linkage disequilibrium. This variability exists among both racial and ethnic groups.

The HLA genes exist in linkage disequilibrium, also referred to as gametic association. Gametic associations are regularly found between certain HLA alleles of A and B, C and B, B and DRB1, and DRB1 and DQB1 loci. The HLA genes are transmitted in families as haplotypes. The number of possible haplotypes is vast. However, because of linkage disequilibrium, the number of haplotypes found in a population is more limited.[8,17] Genetic recombination or crossing over in the HLA region is a relatively rare event, occurring for the most part no more than 1% per meiosis between A and B, and between B and DRB1. Recombination can also occur between A and C, and between B and C (0.6% and 0.2%, respectively).

TABLE 41-4 Names of the Most Important HLA Class I and Class II Genes and Their Encoded Polypeptide Ordered from Telomere to Centromere

Name	Encoded Polypeptide
HLA-A	Class I α-chain
HLA-C	Class I α-chain
HLA-B	Class I α-chain
HLA-DRA	DR α-chain
HLA-DRB3	DR β3-chain determining DR52 specificities
HLA-DRB1	DR β1-chain determining specificities DR1, DR2, DR3, DR4, DR5, etc.
HLA-DQA1	DQ α-chain
HLA-DQB1	DQ β-chain
TAP2	ABC (ATP binding cassette) transporter (associated with antigen presentation)
LMP7	Proteasome-related sequence (role in loading class I molecules with peptides)
TAP1	ABC (ATP binding cassette) transporter (associated with antigen presentation)
LMP2	Proteasome-related sequence (role in loading class I molecules with peptides)
HLA-DMB	DM β-chain (control peptide loading by class II molecules)
HLA-DMA	DM α-chain (control peptide loading by class II molecules)
HLA-DPA1	DP α-chain
HLA-DPB1	DP β-chain

Historical Applications of HLA Typing

HLA allele identification has been used for transplantation, forensic, parentage, and chimerism testing. The latter three are of historical interest and are discussed in this section.

Forensic DNA Testing

The first case in the United States in which DNA-based identity testing was used, *Pestinikas v. Pennsylvania* (1986), involved HLA-DQA1 oligonucleotide, dot-blot hybridization analysis for forensic identification. This commercially available DQA1 system was later modified with five additional non-HLA genetic loci, resulting in discriminatory power of approximately 1 in 2000. The relatively low discriminatory power and problems with interpreting mixtures resulted in the migration of forensic laboratories to other methods and genetic loci as described previously.

Parentage Testing

The use of the HLA loci for parentage testing has been replaced by methods described later in this chapter. The polymorphism of the loci was first inferred from antisera that distinguished among antigenic specificities. These specificities were especially numerous within the Class I loci and it was recognized that they could be exploited in identity testing. Typically, a panel of serological reagents was employed that defined HLA loci and red cell antigens. The emergence of many highly informative non-HLA polymorphic loci that could be conveniently genotyped led to a reduced utility of the HLA loci for parentage testing in the 1990s.

Chimerism

While the HLA loci can be used to study the engraftment of transplanted hematopoietic stem cells (see later in this chapter), other more convenient loci are genotyped for this purpose. These other loci are essential when the transplant donor recipient pair are HLA-identical siblings or allele-matched unrelated individuals.

Transplantation

Matching the HLA alleles of donors and recipients for renal transplantation improves long-term graft survival of kidneys from living related and unrelated donors and from deceased donors. For example, the half-life survival for a graft from an HLA-identical sibling is 23 years compared with a one haplotype–related donor with a half-life of 12.8 years.[10,26] Importantly, the effect of HLA matching remains significant even with the most recent forms of immunosuppression. The effect of HLA matching on the survival of heart and lung transplants is also statistically significant. In contrast, the effect of HLA matching for liver transplants is uncertain.

Hematopoietic cell transplantation (HCT) is employed to treat several classes of disorders. HLA compatibility between donor and recipient in HCT affects not only the ability to achieve sustained engraftment of donor HCT but also the

risk of developing acute and chronic graft versus host disease (GVHD). Posttransplant risk of graft failure, GVHD, and mortality can be affected by quantitative and qualitative characteristics of donor-recipient HLA allele mismatching. In allogeneic stem cell transplantation, the donor is an individual who is genetically nonidentical and either related or unrelated to the recipient. Three different categories of donors are usually considered in the following order of preference: HLA genotypically identical siblings, HLA mismatched relatives, and unrelated donors, matched or mismatched. The goal when screening for an HLA-matched sibling donor is to identify which of any siblings have inherited the same HLA haplotypes from their parents.

HLA typing within families for transplantation sometimes leads to the discovery that the father is not the biological father of some or all of the children. There are a variety of opinions among healthcare providers about whether this possibility should be discussed with the family before testing and how or whether "false paternity" should be reported to the family.

When a matched sibling donor does not exist for a patient requiring allogeneic HCT (70% of cases), searching for extended family members or donors from an unrelated bone marrow registry would be the next option. Registries of volunteer bone marrow donors and cord blood exist in most developed countries (http://www.marrow.org). Currently, approximately 65% of patients can find an acceptable donor among the 4 million individuals registered in the U.S.-based National Marrow Donor Program (NMDP). However, patients belonging to racial groups that are not well represented in the registries have a considerably decreased probability of finding a donor (http://www.marrow.org).[3]

DNA-Based HLA Allele Identification

Most commonly used molecular diagnostic methods have been used to identify HLA alleles. Strategies based on oligonucleotide probe hybridization, DNA sequencing, and allele-specific DNA amplification have become the most common ones used currently for HLA typing. Each of these methods relies on amplification with PCR of genomic DNA of relevant regions of an HLA gene from the tested individual.[10] Samples for testing are usually peripheral blood but may be any tissue containing nucleated cells.

Typing methods involve the design of primer pairs that are able to amplify all alleles at the target HLA locus with the polymorphic sequence motifs situated between the primer sites. Laboratories usually amplify at least exons 2 and 3 of class I genes and exon 2 of class II genes. Some prepare larger amplification products that include exon 1 and/or exon 4 of class I genes. Amplification primers may be located within exons or introns. Primers positioned in introns allow complete analysis of exons and inspection of exon/intron junctions for splice site polymorphisms. Primers must be carefully chosen to attain locus-specific amplification since the HLA loci are the products of gene duplication and divergence and retain substantial homology. Further, many HLA loci have closely related pseudogenes that do not encode functional polypeptides but may result in nonspecific PCR products.[10]

The amplicons prepared are subsequently analyzed by a variety of methods. They can be hybridized to oligonucleotide probes in reverse or forward dot-blot assays. The panel of probes is chosen to cover critical polymorphic positions in the HLA gene tested. The pattern of reactivity of the panel can then be analyzed to assign allele identities.[10]

Alternatively, amplicons can be directly sequenced via dideoxynucleotide chain termination methods. This approach is increasingly attractive for allele level typing because of the large numbers of alleles known to exist at the HLA loci. The homozygous or heterozygous sequence obtained can be compared with a library of known sequences of alleles for allele assignment.[31]

A third commonly employed method, sequence-specific primer PCR (SSP-PCR) employs pairs of PCR primers chosen so that their 3′-most nucleotide or nucleotides are complementary to a polymorphic position that distinguishes an allele or an allele group from other alleles. If the individual possesses the allele(s) of interest, the PCR will lead to a product whose size and presence are typically identified by agarose gel electrophoresis or can be detected with real-time methods. A typing can be performed by choosing many pairs of primers in independent reactions to cover all allele groups.[10]

Commercial reagents and software for analysis of results are available for each of these three methods. Laboratories tailor HLA typing assays to the specific applications discussed above. Choice of methods depends upon typing volume, turnaround requirements, and the resolution needed.

Interpretation of HLA Test Results

The number of alleles at the HLA class I and class II loci, and a listing of serologically defined specificities and their allele equivalents, are available online at several Web sites (http://www.anthonynolan.com/HIG, accessed April 1, 2004 or http://www.ebi.ac.uk/imgt/hla/, accessed April 1, 2004). The alleles of each of the HLA antigens are numbered based on the original serological nomenclature. HLA alleles are now designated by a superscripted asterisk after the locus of origin and a number corresponding to the particular allele (e.g., HLA-A*0201). Parallel testing using serological and DNA genotyping of HLA alleles has led to the use of one nomenclature for the description of low-resolution typing in which the HLA assignment might include more than one possible related allele (e.g., HLA-A A*02) and a nomenclature reflecting the high-resolution allelic typing. Thus different HLA allele subtypes (e.g., for A*02) can appear indistinguishable when tested by serology or with a limited panel of nucleic acid probes so a generic or low-resolution typing is obtained. New HLA alleles are named by an inter-

national nomenclature committee. Annual HLA nomenclature reports with frequent updates are available at the Web sites listed above.

Quality Assurance and Quality Control Issues

Quality control and assurance programs for HLA testing should be similar to those for other types of PCR-based testing. The NMDP and the American Society for Histocompatibility and Immunogenetics (ASHI) maintain a cell repository of a subset of known alleles (http://www.ashi-hla.org/, accessed April 1, 2004). As in other PCR-based testing, strict measures to prevent contamination of pre-PCR areas with genomic DNA and PCR products are essential. Importantly, testing for contamination arising from products prepared in SSP-PCR can be challenging because the many PCR reactions necessary to type an individual often result in products varying in size and composition. Measures to prevent contamination in PCR-based testing have been widely described; such information is available online at the ASHI Web site.

Proficiency Testing

Several proficiency testing programs are available in the United States. These include the College of American Pathologists (CAP), ASHI, and the Southeastern Organ Procurement Foundation. Each offers comprehensive programs to assess laboratories' ability to correctly identify HLA alleles. The University of California at Los Angeles has offered an international cell exchange program for many years. Laboratories are challenged to correctly type samples that often include unusual or recently described alleles.

Accreditation and Certification of Laboratories and Professionals

Clinical histocompatibility laboratories are high complexity laboratories that must have a CLIA license in the United States. Laboratories may be inspected and accredited by CAP or ASHI. The United Network for Organ Sharing, NMDP, and CLIA have all designated ASHI with deemed status for purposes of accreditation of HLA laboratories. Laboratories are generally directed by individuals with Ph.D., M.D., or both degrees. ASHI administers a program to assess the qualifications of doctoral level individuals to direct ASHI-accredited laboratories. Directors can take a certifying examination administered by the American Board of Histocompatibility and Immunogenetics (ABHI). The ABHI also certifies laboratory staff as histocompatibility technologists and specialists. Information is available on the ASHI Web site.

CHIMERISM AND HEMATOPOIETIC CELL ENGRAFTMENT ANALYSIS

Successful HCT effectively results in chimerism with the recipient's hematopoietic cells derived from the donor. With the exception of monozygotic twins, it is virtually always possible to use polymorphic loci on chromosomes to distinguish between DNA prepared from cells derived from the recipient and cells from the donor. This is true even for siblings if enough loci are studied. Suppose the father and mother of two siblings have alleles j and k and s and t, respectively, at a locus. The likelihood that the two siblings will inherit an identical genotype such as js or jt at this locus is 1 in 4. The likelihood that the siblings will be identical for other studied loci for which the parents are similarly heterozygous is also 1 in 4. In this particular example of complete parental heterozygosity, the risk that no locus will be found at which the two siblings can be distinguished is 1 in 4^N where N is the number of independently segregating loci tested. Commercial engraftment testing reagents that include 9 to 16 independently segregating loci will virtually always reveal at least a single locus at which donor and recipient cells can be distinguished.

Methods for Performing Engraftment Analysis

Sources of DNA for engraftment testing are typically peripheral white blood cells or bone marrow aspirates. It is crucial to obtain genomic DNA samples from the recipient before the transplant to determine his or her native genotypes at the tested loci. Then posttransplant samples can be compared with "pure" specimens from the donor and from the pretransplant recipient. If a pretransplant sample from the recipient is not available, another sample such as buccal cells may be obtained. Care should be taken in interpreting results from these alternate sources, however, since donor-derived inflammatory cells may be present.

Testing can be performed on genomic DNA isolated from the entire cell population of the specimen. Alternatively, the sample can be sorted by flow cytometry or immunorosetting to assess engraftment of specific cell lineages.[12] For example, engraftment of the T-cell versus non–T-cell components can be assessed after flow cytometry sorting based on expression of the CD3 surface molecule, a T-cell marker.

DNA typing methods used in engraftment analysis are summarized in Table 41-5. These methods have evolved like those used for identity testing in general. Initial methods relied on Southern blotting to detect RFLPs or VNTRs. These labor-intensive hybridization assays have been largely replaced by PCR-based methods.

One PCR-based strategy is to amplify a series of VNTR loci with subsequent separation of the DNA fragments on polyacrylamide gels.[23] Alleles can be assigned via comparison with size standards after staining with ethidium bromide. The sensitivity of this method for detecting a small admixture of donor or recipient DNA is roughly 10%. Sensitivity can be increased to the <1% to 1% range with silver staining of the amplification products.

As described earlier in this chapter for forensic identification, fluorescent detection of PCR products derived from STR, or microsatellite loci, has been adopted by many labo-

TABLE 41-5 DNA Typing Methods Used in Engraftment Testing

Method	Description	Comment
RFLP analysis of VNTR loci	Digest genomic DNA with restriction endonuclease and detect polymorphic VNTR loci by Southern blotting	Highly informative identity testing method also used in early forensics, now discarded because of its labor-intensive nature
PCR analysis of VNTR loci	Amplify VNTR loci and size by gel electrophoresis	This assay can be quite sensitive when bands are detected by silver staining
STR analysis	Multiplex amplification of several STR loci with sizing by fluorescent detection	Becoming the standard method in the field because of the efficiency and partial automation
Cytogenetics	Interphase analysis of X and Y chromosomes with fluorescent in situ hybridization	May be useful when donor and recipient are of different genders

ratories for engraftment assays.[22] This method is attractive because of the ability to automate the assay, fewer problems associated with "stutter bands," the extensive characterization of these loci in a variety of populations, and their high degree of polymorphism. Surveys from the proficiency testing programs described below indicate that the majority of laboratories providing clinical engraftment testing currently analyze STR loci.

When the donor and recipient are of different genders, analysis of the sex chromosomes in posttransplant hematopoietic cells can be useful in engraftment testing. Cytogenetic analysis of chromosomes in interphase cells with X- and Y-specific probes may be performed with fluorescent in situ hybridization assays. The percent donor or recipient cells can be determined by assessing the ratio of cells with XX signals to those with XY signals. Alternatively PCR-based analysis of X- and Y-chromosome loci can be carried out. For example, the reappearance of Y-specific amplification products in a male whose donor was his sister may indicate relapse of a malignancy. Polymorphic loci on chromosome X can be studied similar to the autosomal STR discussed above.

Selection and Interpretation of Short Tandem Repeat Loci

Engraftment testing is accomplished by preparing genomic DNA from donor and pretransplant and posttransplant recipient specimens followed by PCR amplification of the selected STR loci. Amplification reactions are typically multiplexed using fluorescently labeled commercially available reagents as described above for forensic identity testing. Products are then separated via high resolution slab or capillary electrophoresis on an automated genetic analyzer. Comparison of DNA fragment sizes with a reference ladder allows software to assign alleles for each locus.

The analysis of a donor sample and a pretransplant recipient sample allows the laboratory to identify which STR loci are informative (nonidentical genotypes) for the pair. A posttransplant sample can then be studied. If only fluorescent peaks from the donor are observed, then the cells studied are donor in origin. Rarely, only recipient peaks will be seen, consistent with recipient origin of the cells. These assays can detect admixtures of cell populations down to approximately 3%. Therefore, results indicating that a sample is exclusively from the donor are often reported as >97% donor. If fluorescent peaks derived from both the donor and the recipient are seen, the sample must be a mixture of cells from the two individuals.

The percent recipient in a mixed sample can be calculated by summing the intensities of the informative recipient peaks and dividing by the sum of the intensities of the informative recipient and donor peaks. Many laboratories then average the percent recipient for each locus to arrive at a final result. Some laboratories run a calibration curve of artificial mixtures of donor and recipient DNA for each tested pair. Other laboratories validate the assay with calibration curves for a number of control "donor" and "recipient" mixtures, and do not run new calibration curves for each new donor-recipient pair.

Applications of Microsatellite Locus Testing to Engraftment Analysis

Several clinical questions can be answered with engraftment testing.[27] Is engraftment of donor cells proceeding well in the weeks following a stem cell transplant? In the setting of a history of successful engraftment, do subsequent studies demonstrate a resurgence of recipient-derived hematopoietic cells indicating a relapse? Has stable chimerism developed following transplantation with the production of hematopoietic cells derived from both the donor and recipient?

The correlation of engraftment testing results with the clinical history is crucial for interpretation of results. Thus appropriate communication between the engraftment testing laboratory and the transplantation team is essential.

Consultation with a hematopathologist may be helpful in interpreting results in complex cases.

A result indicating 85% donor cells and 15% recipient cells might be equally consistent with an engrafting marrow 3 weeks after transplantation or with relapse 6 months following transplantation. The date of the transplant in relation to sample collection, the conditioning regimen used before transplant, and evidence from peripheral smear or bone marrow aspirate examination may be helpful in interpreting results. Unusual history, if unknown, can cause considerable confusion. For example, some recipients may have received more than one stem cell transplant or may have had a donor who is an identical twin.

The interpretation of an engraftment result from a single sample can be difficult. Multiple samples collected at intervals after transplantation may reveal changes in the fraction of donor and recipient over time that can be correlated with the evolving clinical picture.

Proficiency Testing

Proficiency testing programs for engraftment testing are offered by the CAP and the ASHI. Challenge specimens are typically artificial mixtures of genomic DNA from two related or unrelated individuals. In both surveys, participant laboratories have demonstrated a high degree of agreement for challenge samples. The standard deviation from the mean of participant results in a 50-50 mixture of "donor" and "recipient" cells is typically ±2% to 4%. For mixtures that approach the sensitivity threshold of the assay (for example 6% recipient, 94% donor) somewhat broader standard deviations may be seen.

Quality Assurance and Quality Control

Quality control and assurance programs for engraftment testing should be similar to those for other types of identity testing. Assays may require as little as 1 ng of genomic DNA. Thus strict measures to prevent contamination of pre-PCR areas with genomic DNA and PCR products are important.

Accreditation

Accreditation of programs may be through the ASHI or the CAP. Since engraftment testing is a variant of identity testing, the standards used are often those written for paternity and other forms of identity testing. However, because engraftment testing deals with subpopulations of cells and the relative proportions of cells, organizations such as the ASHI have developed accreditation standards specifically for engraftment testing.

PARENTAGE TESTING

Questions regarding the parentage of minor and adult children arise frequently in modern society. Generally at issue is whether a particular man is the father of a child. As discussed in the chapter introduction, parentage testing allows an individual to be excluded or not excluded as the parent of a child. If not excluded, the likelihood that he is the father can be calculated. Court-ordered and privately sought parentage testing is usually performed to facilitate decisions regarding responsibility for the financial support of a child. However, there are other reasons individuals may wish to establish parentage; an example is the settlement of an estate. As discussed earlier, laboratories performing other types of identification tests for purposes unrelated to parentage (e.g., HLA typing for transplantation) should be aware of the possibility of inadvertently uncovering "false paternity."

Methods, Instrumentation, and Sample Requirements

Methods for parentage testing have evolved considerably over time similar to other human identification applications. Initial methods relied on serological techniques to identify red cell antigens, such as the ABO and the MNS groups and the highly polymorphic HLA antigens found on most cells. Since 1990 there has been a substantial migration of parentage laboratories to DNA-based methods, especially to those based on analysis of STR alleles. The significant advantages of these PCR-based assays with detection of fluorescently labeled DNA fragments on automated genetic analyzers have been discussed in the section on forensic identification. Recently SNPs have also been introduced in commercial parentage laboratories.

Selection and validation of testing methods are key issues in paternity testing. Specific requirements for paternity testing may be mandated by local laws and agreements. Thus the choice of methods and genetic systems should be based on an agreement between the client(s) and the laboratory.

Nonstandardized methods should not be used as the sole methods within a paternity testing laboratory. In addition, a nonstandard method should only be used if it can be documented that the method is used in at least one other laboratory, thus making it possible to obtain a second opinion based on repeated testing.

Like other forms of identity testing, samples for paternity testing may be any specimen containing chromosomal DNA. In practice, programs generally perform testing on peripheral blood samples or buccal smears. Buccal smears are increasingly preferred as they offer a noninvasive means of sample collection, which is especially convenient when testing minors.

Reporting of Test Results

In addition to the usual paternity test reports, laboratories are occasionally asked to provide interpretative reports when less than complete information is available. The usual report is discussed next and the interpretive reports are discussed afterwards.

Test Reports

The results should include all the information requested by the client and necessary for the interpretation of the test results and all information required by the method used. If the weight of evidence is calculated, it must be based on likelihood ratio principles, such as the paternity index.[2,9]

Exclusion of a Tested Man

Standard parentage testing involves genotyping several polymorphic loci in samples from a trio consisting of the mother, child, and presumed father. Inspection of the alleles found in the mother and the child at the genetic loci analyzed reveals alleles that must have been contributed by the child's biological father. If the accused father does not have an obligatory allele at one of the tested loci, he is excluded as the biological father. Laboratories require the absence of an obligatory allele for at least *two* loci in a tested man to exclude him as the father. The requirement of multiple loci reduces the possibility of making an error caused by a technical problem or caused by a rare mutation at one of the examined loci.

The power of an analyzed locus to exclude a tested man depends upon the number of alleles found at the locus and their allele frequencies in human populations. ABO typing can exclude a tested man but has a relatively poor probability of exclusion of about 15%. The HLA and VNTR loci have many alleles and a single locus may have greater than 90% probability of excluding a falsely accused man. The STR loci have an intermediate number of alleles. A single STR locus typically has a 30% to 60% likelihood of excluding a wrongly accused man. The ease of STR analysis makes these loci attractive for parentage testing even with their lower exclusion power. If a number of STRs that independently segregate during meiosis are studied, a cumulative probability of exclusion can be calculated based on the product of exclusion power for each tested locus. The use of 9 to 16 unlinked, and therefore independent, STRs provided in commercially available human identity reagents generally results in at least a 99% probability of exclusion of a falsely accused man.

Inclusion of a Tested Man

The alleles found at the analyzed loci may be entirely consistent with the accused man being the biological father of the child. In this case, the likelihood that he is truly the father rather than a random individual who is not excluded can be calculated. A number of assumptions underlie accurate calculations of the likeliness of paternity. Tested individuals must be properly identified, testing must be accurate, and allele frequencies in relevant populations must be well characterized.

The probability of paternity (W) and the paternity index (PI) are two closely related values that express the likelihood that the tested man is truly the father rather than another man who by chance shares alleles at a tested locus. Calculation of the PI takes into account allele frequencies at the locus in relevant populations. If multiple independent loci are analyzed, a cumulative PI based on the products of the individual loci can be calculated. Government entities typically require that the paternity index be >100:1 and the probability of paternity be >99% for inclusion of a man. Other evidence bearing on the probability that a man is the father before testing is performed can be integrated with test results using Bayesian analysis to calculate a posterior probability of paternity. The prior probability that an accused man is the father is typically set at 50%, but a range of likelihoods given different prior probabilities (e.g., 10% to 50%) can be calculated for comparison.

Opinions, Interpretations, and Problems

Standard parentage testing requires samples from the trio described above. However, there are many cases in which the mother, child, and putative father may not all be available for testing. If a sample cannot be obtained from the mother it may still be possible to exclude a tested man or to calculate his probability of paternity. For example, the finding of locus L genotypes 1,3 for the child and 4,5 for the tested man is inconsistent with the hypothesis that he is the father whether or not we know the mother's genotype. Similarly, when the accused man is not available, testing performed for individuals related to him may be used to calculate the likelihood that he is the biological father of the child in question.

While STRs and VNTRs are usually transmitted in a faithful Mendelian fashion, mutations can occur. A child and tested man may be encountered who share an allele at all but one of the tested loci. The possibility that the man is truly the father and that a mutation has occurred at the mismatched locus should then be entertained. If additional loci are tested with no additional genetic inconsistencies discovered, the likelihood of paternity can be calculated by considering the frequency of mutations at the mismatched locus. Alternatively, additional genotyping may reveal more exclusions, making it unlikely that the tested man is truly the father. Laboratories should apply procedures for estimating uncertainty of measurement. The measurement of uncertainty of tests should be known and should be included in the interpretation of test results.

Quality Assurance and Quality Control

The quality control and assurance measures for paternity testing are similar to those for other types of human identity testing. Positive identification of samples, prevention of DNA contamination, the use of control alleles of known size, and the validation of software employed for genetic analysis and calculation are among measures common to identity testing programs. Population distribution data for the systems used must be documented. In addition, mutation frequencies of the systems used must be documented and used appropriately.

Policy and Procedures for Resolution of Complaints

The laboratory should have a policy and procedure for the resolution of complaints received from clients or other parties. Paternity testing programs involving knowledge of sensitive family information results may be employed in legal proceedings. Samples and records including information stored electronically must be handled carefully to ensure their privacy, confidentiality, and security. Laboratory procedures for documentation of the identity of individuals contributing samples for study and the chain of custody of specimens should be very detailed.

Accreditation

Recommendations and standards for paternity testing are formulated by government agencies or professional organizations (e.g., the Standards for Parentage Testing Laboratories of the American Association of Blood Banks [AABB]). The AABB administers a laboratory inspection and accreditation program.[1] The ASHI and CAP also publish relevant standards. The CAP and AABB jointly offer a proficiency testing survey.

CHAPTER 42

Molecular Methods in Diagnosis and Monitoring of Infectious Diseases

Andrea Ferreira-Gonzalez, Ph.D., and Angela M. Caliendo, M.D., Ph.D.

In the short time since their introduction, nucleic acid tests have profoundly affected the management of infectious diseases. In contrast to microbial culture methods, "molecular" methods are rapid, thus allowing early decisions about treatment to be based on data about the pathogen(s) in an individual patient. Molecular methods have provided a means to detect pathogens that could not be easily detected by traditional methods such as culture, antigen detection, or serology. By rapidly providing quantification and sequences of nucleic acids in pathogens, the methods have transformed the approaches to prediction and monitoring of response to therapy, assessing risk of disease development, and determining disease prognosis.

The first third of this chapter reviews concepts in the development and clinical implementation of molecular assays for testing in infectious disease. Readers with backgrounds in analytical techniques or molecular testing or infectious diseases may wish to use the headings in the text to identify the parts of interest to them. The later sections of the chapter describe nucleic acid testing for specific pathogens, with a new section heading for each pathogen or pair of related pathogens. These sections include discussion of the clinical utility of the testing and are focused on those pathogens for which molecular testing is considered the standard of care. Because the field is expanding rapidly, we provide links throughout the chapter to Web sites where recent developments can be monitored.

DEVELOPMENT OF MOLECULAR ASSAYS FOR INFECTIOUS DISEASES

Molecular infectious disease laboratories use methods developed by in vitro manufacturers and assays developed by individual laboratories. Complete reagent sets developed by manufacturers are provided with quality-controlled reagents that have been manufactured under Good Manufacturing Practices (GMP), and the performance of the entire molecular test has been determined for a particular clinical claim. For example, a number of reagent sets and complete systems of reagents and associated instrumentation are commercially available for the diagnosis of sexually transmitted diseases caused by *Chlamydia trachomatis* (CT) and/or *Neisseria gonorrhoeae* (GC), as are systems for monitoring disease progression in patients diagnosed with human immunodeficiency virus-1 (HIV-1) infection by quantification of HIV-1 RNA in plasma specimens. These products usually include reagents for nucleic acid isolation, amplification, and detection/quantification with a specific protocol. In the United States, they are commercialized using different labels depending upon U.S. Food and Drug Administration (FDA) status and review including FDA-approved, FDA-cleared, for research use only (RUO), or for investigational use only (IUO).

Nucleic acid–based testing for infectious diseases, as for other clinical conditions, usually involves three major steps: specimen processing, nucleic acid amplification, and

product detection. Several systems automate one or two steps, and automation of all three steps in a single analyzer is expected from manufacturers in the near future. It is expected that these systems will be capable of integration with common laboratory information systems, thus creating another major advance for clinical microbiology laboratories and facilitating reporting of results in timeframes that allow more rapid institution or alteration of therapy.

Many clinical laboratories find it necessary to develop methods to detect various infectious agents for which there are no commercially available methods or systems. Laboratory-developed tests (LDT), formerly known as home-brew assays or in-house developed assays, are those assays that have been fully developed and validated by the laboratory that offers the testing. Usually, these assays use a combination of reagents that are purchased separately from various manufacturers. The analytical and clinical verification of the LDT is the responsibility of each laboratory, and this verification procedure is more complex than verification of an FDA-cleared or FDA-approved test.

Analyte-Specific Reagents

In the United States, the jurisdiction of the FDA includes reagents, equipment, and complete assays used in diagnosis or treatment of disease. The FDA introduced the term analyte-specific reagent (ASR) to refer to such reagent(s) used in LDTs that confer specificity for detecting a particular analyte.[58] ASRs include antibodies, specific receptor proteins, ligands, and oligonucleotides. Because of the importance of ASRs in infectious disease testing, we summarize key points of the regulations here.

The FDA considers LDTs medical devices subject to FDA regulatory oversight, but with very few exceptions has not executed this authority (the high complexity laboratories that develop LDTs are regulated by the Center for Medicare and Medicaid Services under the provisions of the Clinical Laboratory Improvement Act [CLIA] of 1988). With the ASR category, the FDA shifted its focus from the laboratory to the manufacturers of reagents, and proposed controls and restrictions to ensure their quality and consistency, and to clarify that a laboratory setting up these tests is responsible for the tests' performance.

Manufacturers are restricted in the distribution, use, and labeling of ASRs, and can sell them only to CLIA-certified, high-complexity laboratories. They must register and list ASRs with the FDA, follow GMP, and report adverse events that result from product failure. Most of these products are exempted from premarket review, but are subject to restricted labeling and use. The labeling of these reagents is restricted to "description of the identity and purity including source and method of acquisition of the ASR, in addition to standard information already required for general purpose reagents," with the specific disclaimer reading: "Analyte-specific reagent, analytic and performance characteristics are not established." Furthermore, manufacturers are forbidden from labeling and/or promoting ASRs, including any statements about the ASR's analytical performance, clinical performance, or diagnostic ability. Commerce of ASRs to in vitro diagnostic (IVD) manufacturers or nonclinical organizations (academic, research, and forensic settings) is exempt from the ASR rule.

The FDA has mandated that laboratories using ASRs must label their reports with the statement, "This test was developed and its performance characteristics determined by (laboratory name). It has not been cleared or approved by the U.S. Food and Drug Administration." LDTs that use primers and probes made in the laboratory are not covered by this rule. The College of American Pathologists (CAP) has suggested additional language to reflect the fact that FDA review is not required under this regulation.

When to Use a Molecular Test for an Infectious Disease

A new test should provide reliable, cost-effective, and timely results necessary for diagnosis and management. Test selection should not be based solely on cost. Performance characteristics and impact on patient care and management are critical components of the decision. New tests can improve patient care and decrease its cost as in the use of genotyping of HIV-1 to detect drug resistance.[76] This testing added a new cost, but allowed rapid and accurate determination of the potential effectiveness of expensive drugs. This improved clinical outcomes and decreased the incidence of virological failures and the total cost of treatment. The ability of molecular assays to enhance clinical care in infectious disease often arises from increased diagnostic sensitivity and specificity and shortened turnaround time.

Both clinicians and laboratorians are key players in identifying the testing needs of a medical center. The technical capabilities within the laboratory must be assessed in relation to the clinical needs. Consideration must be given to the interconnected issues of test volume, required turn-around time, and costs of performing the assay. An adequate testing volume is important to maintain proficiency of personnel and to control cost. Rapid turnaround for most tests in infectious disease implies testing of single samples rather than batches, with increased costs. As development and validation of LDTs are costly, it is best to determine if a similar assay is pending FDA review.

Patented procedures and sequence information affect decisions about testing. It is not always clear whether a technology or sequence has been patented or, if so, who owns the patent. It is thus advisable to check with the investigators who first described the sequence and to review the patent database and pending patent databases (United States Patent and Trademark Office Home Page: www.uspto.gov).

Choice of Specimen to Test and Analytical Approach

After a clinical need has been identified, a thorough literature search should be carried out to characterize the clinical utility of testing and its relation to specimen types, deoxyri-

bonucleic acid (DNA) or ribonucleic acid (RNA) targets, and testing methodologies, whether qualitative or quantitative. For example, in distinguishing clinically significant cytomegalovirus (CMV) disease from asymptomatic CMV infection in immunocompromised individuals,[155] the detection of viral nucleic acid is not informative, and quantitative assays are necessary. Similarly the choice of RNA or DNA affects the ability to distinguish disease from nondisease status. Careful consideration should be given to the advantages and disadvantages of potential methodologies and the laboratory capabilities and the abilities necessary to ensure successful test development.

Test Development

Target sequences must be chosen to prevent cross-hybridization with other known sequences. A preliminary evaluation of published protocols or use of generic default concentrations for polymerase chain reaction (PCR) components can be a useful starting point. Modifications in assay design may be necessary depending on the specimen type. For example, if using fixed paraffin-embedded tissue as the specimen source, one might want to limit the size of the amplified product since tissue fixation can significantly affect nucleic acid quality and consequently affect the ability to amplify long nucleic acid sequences.

After initial tests, the next step is to optimize steps of the analytical process, including nucleic acid extraction, amplification, detection, and quantification. For amplification procedures, variables to be optimized may include buffer pH, nucleotide concentration, $MgCl_2$ concentration, type of polymerase, primer concentration, and annealing temperature.[74,90,191]

Preanalytical Variables

Common preanalytical variables include specimen type, specimen volume, anticoagulant, and specimen transport, storage, and handling. The type of specimen that is acceptable for testing will be largely determined by the pathogenesis of the disease and plays a key role in the performance and interpretation of the test results. Molecular assays often offer the convenience of using a small, less-invasive specimen. The diagnosis of herpes simplex virus (HSV) encephalitis is a classic example, where culture of brain biopsy has been replaced by PCR testing of a small volume of cerebrospinal fluid (CSF). Although molecular tests can detect the presence of small numbers of organisms, the probability of detection increases when a larger volume of specimen is added to the amplification reaction. This reflects in part the probability of having any organisms in the tested volume of sample. Because molecular assays do not need viable organisms for testing, more flexibility in specimen transport is possible than for culture methods.

Appropriate specimen collection and transport conditions are critical to ensure nucleic acid integrity, especially for quantitative methods, and to prevent cross-contamination of specimens. The appropriate specimen type, timing of specimen collection, and specimen handling will depend on the clinical presentation of the disease, the pathobiology of the infection, and the type of nucleic acid required for the test. The format of the molecular assay being developed may affect the amount of specimen required. Specimen transport and storage conditions are likely to vary among specimen types and between RNA and DNA tests. They will vary depending upon the need for viable or intact cells or microorganisms and must be determined by each laboratory. RNA is especially susceptible to degradation by ubiquitous enzymes. Specimens may be stable at room temperature for days or may require, for example, separation of plasma from cells within a few hours of collection and either immediate testing or storage of the plasma at −80 °C until testing is performed. Adding a known amount of purified target, microorganism, or cells to target-negative specimens can be useful in efforts to assess the preanalytical variables. Detailed written instructions for specimen collection and for handling and transport should be provided to those individuals involved in these tasks and duties.

Internal Controls

Internal controls, which are added to the clinical specimen before processing, are often used to detect the presence of inhibitors of amplification or to determine if nucleic acid degradation occurred during specimen processing. Internal controls are often synthetic segments of nucleic acid that use the same primer sequence as the target molecule, with a portion of the sequence internal to the primer binding sites that is unique to the internal control. This allows simultaneous amplification of the internal control and target, but separate detection using sequence-specific probes or physical separation of the two products by size. Internal controls and the target sequence must have the same or very similar efficiencies of amplification, and thus they must have similar length and base composition.

Failure to amplify the internal control may be due to nucleic acid degradation, inhibitors of amplification, or amplification failure. Regardless of the cause, when the internal control is not detected the assay is invalid.

A low amount of the internal control is used to avoid competition with the target in the patient specimen and to detect low levels of inhibition in the reaction. Amplification of a housekeeping gene can be used in place of an internal control when detecting or quantifying nucleic acid from a cellular specimen or tissue. However, most of the housekeeping genes are highly abundant, and thus subtle losses of nucleic acid or inhibition of amplification may not be detected. The use of RNA from a gene with a similar approximate abundance as the target sequence is preferred.

Nucleic Acid Extraction

Several commercially available manual and automated methods have been successfully applied to infectious disease testing of a wide variety of clinical specimens. These methods are rapid, usually require only a small volume of

specimen, and provide more consistent results than older methods. In addition, the commercially available approaches can reduce hands-on labor requirements, and many can accommodate sample volumes ranging from 100 µL to 500 µL and even 1 mL of specimen.

Quantitative Molecular LDTs

Quantitative methods for DNA and RNA (reviewed in Chapter 37) are widely used in infectious disease testing to determine, for example, the viral load of agents such as hepatitis C virus (HCV) and HIV-1. Quantification requires a reproducible relationship between the amount of input target and the output signal from the assay. The concentration of analyte in a sample is determined by comparison of the signal from the sample with that from calibrators of known concentration. External calibrators avoid competition with the target sequence for reaction components, such as nucleotides, and can be naturally occurring—exactly matching the target of interest. The major disadvantage of external calibrators is that they are analyzed in a different reaction from the patient specimen and thus are not subject to the same reaction efficiencies or inhibition as the target sequence in the patient specimen. External calibrators are used for the quantification of HIV-1 in patient specimens using bDNA technology.[131] More recently, external calibrators have been used with good success to quantify nucleic acid present in patient specimens by real-time PCR technology.[83,103,177]

An internal calibrator can be synthesized in vitro to contain the same primer binding sequence as the target of interest, but with a different sequence internal to the primer binding sites. This allows the calibrator and the target sequence to be differentiated by using sequence-specific probes, as described above, for the internal control.

Internal calibrators compensate for inhibitors and/or loss of nucleic acid during the nucleic acid extraction procedure, but they (like internal "amplification controls") can compete with the target sequence for assay components and result in lower quantified result or no result at all. Since internal calibrators have some variation in sequence compared with the target to enable specific detection, natural analytical materials do not make good internal calibrators.

When amplifying nucleic acids from cells or tissues, amplification of a housekeeping gene may be used as an internal control and even as a calibrator. It is important to understand that these internal calibrators might be present at a much higher concentration than the target of interest and might also compete for reaction reagents, providing an inaccurate quantification of the target.

TEST VERIFICATION

Verification of a test is a complex process that can be divided in two phases: analytical and clinical verification. Analytical verification provides critical information about the performance of the test, while clinical verification establishes the clinical indications for the test. Determination of the clinical indications provides information about the appropriate settings, including disease states and populations for which the test can be used. Table 42-1 provides a list of guidelines that can be useful in developing validation programs. In addition, Table 42-2 outlines a checklist to assist in the verification process for a molecular assay.

In the United States, major differences exist between the implementation of an FDA-cleared test versus a non-FDA cleared test. As stipulated in CLIA '88,[59] laboratories implementing FDA-cleared tests need to verify the performance characteristics of the test for the indications for use. On the other hand, implementation of an LDT is a more complex process, as laboratories are required to establish the analytical verification of the test.

Analytical Verification

Laboratories must assess each LDT's detection limit (often called in regulations the "sensitivity"), specificity, accuracy, precision, and linear or reportable range. Verification of a LDT can be challenging when no standard reference material is available. Table 42-3 lists suppliers of reference materials that can be used during analytical verification and as a source of material for quality control purposes. National and international organizations are developing standard reference materials that will be useful for assay verification. The World Health Organization (WHO) recently introduced[157] a standard reference material for HCV for verification of nucleic acid tests. This lyophilized material (HCV 96/790) contains approximately 100,000 genome equivalents per milliliter and was assigned a value of 100,000 International Units (IU)/mL.[157] WHO also introduced an HIV standard, HIV 97/656. Similar to the HCV standard, it consists of a lyophilized preparation of HIV-1-genotype B virus from a plasmapheresis donation. Several laboratories have tested this material with different technologies, obtaining a mean value of 4.79 log genome equivalents/mL, which was assigned a value of 100,000 IU/mL. Finally the WHO hepatitis B virus (HBV) standard 97/746 has been assigned a value of 1 million IU/mL.[125] Reference panels calibrated to WHO standard reference material are commercially available (Table 42-3).

Some laboratories have established their own reference materials for analytical validation. Creating a reference material requires an independently established method for determining target nucleic acid concentration or, alternatively, conducting studies to compare their test with another established assay. For example, samples can be split for a comparison study with another laboratory that performs a similar molecular test. To compare results with another molecular assay, both laboratories should perform a similar assay or at a minimum test for the same target sequence. The samples for testing may be available from one of the laboratories or from an outside source, such as a collaborating laboratory, government organization (the Centers for Disease Control and Prevention [CDC], FDA, or National Institutes of Health), or a commercial supplier.

TABLE 42-2 Checklist for Verification of Molecular LDT

Name of Test	State the name of the test. Be sure that the name identifies the particular organism and/or disease/condition to be tested.
Intended use	What the test measures and for what purpose. Identify the particular microorganism and indicate the use of the test (e.g., diagnosis, prognosis, monitoring response to treatment, guiding therapy, etc.).
Indications for use	Provide clinical condition(s). Use reference standard definitions as found in OMIM.
Method category	Identify methodology used for the test.
Testing procedure	Information with regard to specimen types, specimen handling and transport procedures, nucleic acid isolation and storage, description of the test procedure, data reports, expected results, technical interpretation of results.
Test results	Representative examples of results.
Analytical verification	Analytical "sensitivity," analytical specificity, precision, and linear dynamic range.
Quality control and quality assurance	Delineate QC and QA program. Identify informal proficiency program if no HHS-approved program exists.
Assay limitations	Briefly delineate and discuss potential limitations.
Clinical data	Primary objective of the study, clinical condition evaluated, patient population, demographics, sample size estimate.
Clinical verification	Clinical sensitivity, clinical specificity, positive predictive value, negative predictive value.
Reporting of test results	Clinical interpretation.
Clinical utility	Potential clinical benefit to patient.

OMIM, Online Mendelian Inheritance in Man.

TABLE 42-3 Commercial Sources for Control and Panel Materials

Company	Available Material
Boston Biomedica Inc. (www.bbii.com)	Quantitative and qualitative controls; external run controls; quantification, verification, and performance panels for HCV, HIV, HBV, external run controls for CMV, *Chlamydia trachomatis,* and *Mycobacterium tuberculosis.*
Advanced Biotechnology Inc. (www.bioresearchonline.com/storefronts/abi.htmL)	Control DNA, virus and cell lines (HIV, HTLV, EBV, CMV, HSV, VZV, HCV, SIV, and rubella). Native and recombinant products; purified viruses, antigens, proteins, and antibodies.
Stratagene (www.stratagene.com)	Universal human reference RNA for microarray technology.
AcroMetrix (www.acrometrix.com)	External run controls, secondary reference controls, verification panels for HIV, HCV and HBV, HIV genotyping. Internet evaluation service.
National Institute for Biological Standards and Controls (www.nibsc.ac.uk)	Evaluation/statistics service, working reagents for HIV-1 RNA, HCV, HBV, HAV, parvovirus B19.
Ambion (www.ambion.com)	Armored RNA for internal controls.
American Type Culture Collection (www.attc.gov)	Bacteria, bacteriophages, cell lines and hybridomas, filamentous fungi and yeast, tissue cultures, and viruses.

Reference materials may be naturally occurring or synthetic. "Natural" reference materials are those that consist of a known analyte or known quantity of an analyte as it occurs naturally in the test matrix, purified from the test matrix, or derived by culture of the organism or cell lines. Examples used by a number of laboratories are intact virus particles, bacteria naturally containing the target in their genome, cell lines containing a specific genetic change, or intracellular RNA or DNA. "Synthetic" reference materials include single- or double-stranded DNA, or RNA manufactured in vitro, which are quantified by physical and/or biochemical methods. Such synthetic reference materials can include synthesized DNA in the form of oligonucleotides, single-stranded DNA produced by cloning recombinant phage, cloning into vectors such as plasmids, or a DNA fragment produced by a chemical or physical method from a larger DNA molecule. Synthetic RNA reference materials can be generated by in vitro transcription of DNA templates.

Assessment of analytical characteristics should use test or reference materials that are similar to the intended patient specimen and are carried through the entire process. If possible, precision studies should be performed with more than one lot or batch of reagents and/or materials. Assessment of the accuracy of molecular methods is challenging when, as often happens, the methods have lower detection limits than the established methods.[115,182,183] A well-characterized reference material can be used for accuracy studies.

The linear range of an assay is the span of analyte concentrations for which the final value output is directly proportional to the analyte concentration, with acceptable accuracy and precision. Every assay has an upper and lower limit of quantification, and the lower limit of quantification may be higher than the limit of detection for the assay. The linearity of a quantitative assay may be assessed by testing multiple replicates of at least four different concentrations of the analyte.

Analytical sensitivity (the change of signal per unit change of analyte) is determined by performing serial dilutions of an appropriate number of samples containing known amounts of the analyte. The limit of detection of virus is sometimes defined as the lowest concentration that produces a measurable signal (above background) in 95% of replicates tested. The limit of quantification is the lowest concentration of nucleic acid that can be quantified with an acceptable uncertainty; the uncertainty is often defined in terms of imprecision (coefficient of variation [CV]), which may be as high as 30% for these tests. Analytical specificity is the ability of an analytical method to detect and/or quantify what the test is intended to measure. For infectious disease testing, it is particularly important to ensure that primers and probes do not hybridize with nucleic acid from organisms present in the normal flora or those that cause a similar clinical syndrome.

The susceptibility of the assay to interfering substances must be determined. Exogenous interfering substances are introduced into the specimen, usually during specimen collection or processing. Common examples are heparin and phenol. Both inhibit amplification by polymerases. Endogenous interfering substances, such as bilirubin and lipids, can be increased by disease.

Clinical Verification

The proposed indications for use of the test should be defined before starting the clinical verification. As for any tests (see Chapter 13) the indication for use of an assay could involve the making of a diagnosis, the ruling out of a diagnosis, the provision of prognostic information, or the monitoring of disease—especially, in infectious diseases,

establishing resolution of the disease. Special cases of these indications include the screening of a population (e.g., blood donors) and the confirmation of results from another assay. The first step is to formulate a clinical question (Chapter 13), which should take into account the management decision that needs to be made, the role of the method in decision-making, and the target population to which the test will be applied. Known analytical limitations (e.g., precision and linear range) should be taken into consideration when determining the clinical indication for each assay. Further details are provided in Chapters 13 and 15.

Determining the diagnostic accuracy and clinical utility (Chapters 13 and 15) of an assay can be especially difficult when the molecular assay is more sensitive than the reference standard ("gold standard") test. Viral culture, which has been considered "the gold standard" for many years, is an imperfect reference standard test. An insensitive reference standard can make the molecular assay falsely appear to have a low diagnostic specificity. This situation may require use of an expanded gold standard, including a second nonmolecular method (such as serology), a second molecular assay targeting a different region of the genome, or even clinical diagnosis to ascertain the specificity of the molecular assay. For the study of molecular testing for CT, the expanded reference standard included testing by direct fluorescent-antibody assay and/or another molecular test.

Determination of diagnostic accuracy (Chapters 13 and 15) requires attention to both the population and the type of sample, as the results for a method in a given population using a specified sample type may not apply in another population or for another sample type in the same population. Investigation of the diagnostic specificity should include samples from patients with diseases that might be confused with the indicated disease. Specimens from healthy donors are less useful unless the test is intended for screening. The clinical utility of an infectious disease test can also be affected by factors such as microbial-host interactions, microbial dynamics, variants and mutations, and replicative fitness of the microbial agent.

QUALITY CONTROL AND QUALITY ASSURANCE

Quality assurance programs (Chapter 19) address all aspects of the testing process, from test selection to interpretation and use of results. Further details for molecular testing laboratories are provided in Chapter 38. In the United States, the extent of quality assurance and quality control performed for any molecular assay depends on whether the test is FDA-cleared, is "for research use only," is being used "off-label" (for nonapproved uses), or is an LDT. In general LDTs require more extensive quality control, because the analytical performance must be established and maintained by the laboratory. As a result, LDTs require a quality control program for validating the composition, concentration, purity, and performance of critical reagents of the testing process. Tolerance limits should be established for each of these reagents and whenever possible should use a quantitative measurement to avoid subjective evaluation of the quality of the critical reagent. All new reagents should be tested in parallel or concurrently with the previous lot of reagents.

Careful selection of control material and types of controls is vital for the interpretation of test results. For molecular assays, controls may be necessary to detect inhibition of amplification, to assess adequacy of extraction of nucleic acid from the clinical specimens, or to identify degradation of nucleic acid during the extraction procedure. Negative and positive controls are necessary (and required by CLIA '88 regulations), and both must be processed in every clinical test run. The CLIA '88 final rule (published in January 2003) mandates for quantitative molecular assays a negative and two concentrations of positive control in every run. Failure to obtain the correct result for any of the controls invalidates the run. Positive controls should be at a clinically relevant concentration of the nucleic acid target sequence in a background of nucleic acid lacking the target sequence. A positive control should be present at or near the limit of detection of the assay. Positive control material that resembles a patient specimen can also be used as a nucleic acid extraction control to test the ability of the extraction procedure to successfully release the nucleic acid from the organism.

Available control materials include patient specimens that have been well characterized by a similar method, synthetic controls such as Armored RNA (Ambion Inc., Austin, Texas), or purified nucleic acid, although purified nucleic acid would not be appropriate for use as an extraction control. Armored RNA uses a bacteriophage coat around an RNA target to produce pseudoviral particles. Control material is currently available for a variety of pathogens, including HIV-1, HCV, hepatitis A virus, enterovirus, Norwalk virus, and West Nile virus. These armored RNA preparations are stable for at least 11 months and are compatible with a large number of different platforms commonly used for quantitative molecular assays. Table 42-3 lists other manufacturers of control materials.

To check for inhibitors, an internal control can be added to the sample. Alternatively, two portions of the specimen can be tested, with one of them containing an added target. For a specimen to be considered negative, the test result for the specimen amplified directly must be negative and the specimen with added nucleic acid must be positive. The amount of target nucleic acid added to the patient specimen should be close to the limit of detection of the assay, so that low levels of inhibition can be detected. The use of these controls is often discontinued if the inhibition rate is determined to be less than 1%.

Proficiency testing for molecular diagnostics laboratories remains a challenge because adequate proficiency testing programs are unavailable to cover the wide variety of molecular assays offered by a number of laboratories. The CAP offers the only proficiency program accredited for molecu-

lar infectious disease by the U.S. government. The program covers only a limited number of microorganisms and in certain instances it does not cover the number of challenges required by CLIA '88. Testing is provided for CT and GC, and HIV-1 and HCV quantitative assays, and for *Borrelia burgdorferi*, CMV, HSV, HCV genotyping, HCV RNA, HIV-1 genotyping, human papillomavirus (HPV), mec A, molecular typing-bacterial, and *Mycobacterium tuberculosis* (MTb). Proficiency testing from Acrometrix (Benencia, Calif.) for HIV-1 genotyping and HCV genotyping offers the submitting of results and retrieving of survey summaries via the Internet. The CDC also offers a Model Performance Evaluation Program for detection and quantification of HIV-1 RNA and detection of MTb.

When no external proficiency-testing program is available, laboratories can compare results on "split" samples shared with other laboratories, perform split-sample testing by an established in-laboratory method, or validate test results based on clinical diagnosis. Specific professional organizations, such as the Association for Molecular Pathology, have been instrumental in facilitating split-sample testing among laboratories through sample exchanges for their members. When exchanging samples between laboratories, it is important to identify a laboratory that uses the same procedure or one that detects the same nucleic acid sequence, and for quantitative methods to ensure similar calibration of the tests. This is important, because even viral load values from commercial assays for HIV-1 RNA can differ by as much as tenfold for any given specimen.

The procedure protocol should be written according to specific guidelines, such as those from the National Committee for Clinical Laboratory Standards (NCCLS).[126] The laboratory procedure is one of the most important aids during orientation and training of new personnel along with continuing assessment for trained personnel.

INTERPRETATION OF RESULTS

Interpretation of the results of molecular assays for infectious diseases requires an understanding of the target organism's biology and the pathogenesis of the related infectious disease(s), and the advantages and limitations of the technology used. Some of the challenges in interpreting these tests are unique to molecular tests and may be different from considerations in interpreting other microbiological tests, such as culture and serology. Such differences may relate to distinguishing viable from nonviable organisms and correlating nucleic acid detection with the presence of the disease.

Interpretation of a negative result requires the consideration of assay sensitivity and efficiencies of nucleic acid extraction and amplification. A false-negative result may be caused by inhibition of or decreased efficiency of amplification, and proper controls for this have been described above. Insufficient sample, inappropriate specimen type, inappropriate timing of sample collection, and degradation of nucleic acid during transport and handling are other sources of false-negative results.

The factors that need to be considered when interpreting a positive result include assay specificity and contamination. Here again, assay design plays a key role in result interpretation. Specificity of molecular infectious disease assays is related to the primers and probes used during amplification and detection/quantification steps. If primers allow amplification of nucleic acids from other pathogens normally present in a patient specimen, false-positive results are possible. For example, primers and probes designed for detection of *Mycoplasma pneumoniae* should not amplify or detect other microorganisms present in the normal oral flora or other common respiratory pathogens. While uncommon, problems with primer specificity have been reported; primers designed to amplify the 5′ untranslated region of the enterovirus genome have also been shown to amplify rhinovirus RNA.[153] This will not be an issue if the assay is only used for CSF, but could cause false-positive results if respiratory specimens are tested.

False-positive results can also occur as the result of carryover contamination of amplified products. This is not a problem with signal amplification methods, but can be of significant concern for target amplification methods, such as PCR, nucleic acid sequenced based amplification (NASBA), transcription-mediated amplification (TMA), and strand displacement assay (SDA). The use of real-time assays that do not require post amplification handling of the product greatly reduces the risk of carryover contamination. Cross-contamination of clinical specimens with target DNA during specimen collection, transport, and processing can occur with any method. Strict attention to good laboratory practices is needed to minimize the risk of cross-contamination.

Molecular tests for infectious diseases do not provide information regarding the viability of an organism. Nucleic acid for certain microorganisms can be found for a period of time after treatment is initiated. For example, CT DNA can be detected in the urine of patients for as long as 3 weeks after initiation of the appropriate therapy.[63] Similarly, HSV DNA can be detected in CSF of patients with encephalitis for 2 weeks or longer after initiation of acyclovir therapy.[97] Monitoring of response to therapy with qualitative assays has limited clinical utility and is best done using quantitative methods. One exception is the use of qualitative RT-PCR method to monitor response to treatment to interferon and ribavirin in HCV-positive patients. In this instance, the absence of detectable HCV RNA from plasma or serum specimen is used to define the virological response to treatment.[50,102,141]

Detection of nucleic acid of a pathogen does not ensure that the organism is the cause of the disease. The organism might be forming part of the normal flora, colonizing a specific area, or causing infection but not disease. One of the primary uses of molecular assays for CMV is for distinguishing active CMV disease from clinically insignificant CMV infection. Early studies evaluating the clinical utility of CMV DNA assays used very sensitive qualitative methods and peripheral blood mononuclear cells as the specimen of choice. As a result, CMV DNA was detected in immuno-

compromised patients with and without CMV disease, and even in healthy donors.[99] Several approaches have been used to overcome this shortfall and improve the clinical specificity of molecular assays for the diagnosis of active CMV disease in immunocompromised patients, including development of quantitative molecular methods, use of plasma as the specimen, and detection of CMV mRNA rather than DNA. Cutoff values have been proposed as a means to discriminate infection from clinically relevant disease.[60,111]

A common application for quantitative molecular assays is in monitoring of disease progression or response to therapy over time. To determine if changes in the quantitative values are clinically significant or due to expected fluctuations of the measurement, one must consider analytical and biological variability. For example, for the current HIV-1 viral load assays, to allow for both assay and biological variability, changes in the viral load must exceed 0.5 $\log_{10}$ (a threefold change in concentration) to represent a biologically significant change in viral replication.

REPORTING OF RESULTS

Reporting results for qualitative assays in infectious disease is simple: The nucleic acid is either present or "not detected" in the patient specimen. Further relevant information that is useful when reporting results includes the detection limit and specificity of the test and the rate of inhibition for a given specimen type, particularly for assays that do not contain an inhibition control.

Reporting of results for quantitative molecular infectious disease assays is more complex and requires understanding of intrinsic analytical variables that might affect the test results. Quantitative molecular assay results can be expressed in a variety of units, such as copies, genome equivalents, or international units of the target nucleic acid per unit of specimen. Despite all recommendations of august bodies that the unit of volume be the liter (as in SI units), the unit of volume typically used in clinical microbiology laboratories for specimens such as plasma is the milliliter. Concentrations may also be related to a number of leukocytes (e.g., 10,000) or weight of tissue. Results of viral load assays are usually reported as either copies per milliliter or $\log_{10}$ copies/mL. Reporting results as $\log_{10}$ copies/mL may help prevent overinterpretation of small changes. As with all assays, results above the dynamic range should be reported as greater than the upper limit (i.e., >100,000 copies/mL) and "negative specimens" should be reported as less than the lower limit of the assay (e.g., <400 copies/mL). The limit of detection for an assay may not be the same as the limit of quantification; in fact the limit of detection may be lower than the amount of nucleic acid that can be accurately quantified. So the analyte may be detected in a specimen, but at a concentration below the limit of quantification. These values can be reported with the comment "analyte detected, but unable to quantify." This can be confusing to clinicians; so many laboratories report these as less than the limit of quantification (i.e., <400 copies/mL).

SPECIFIC PATHOGENS

Nucleic acid testing has had a tremendous impact on the practice of infectious diseases. These tests are used in a variety of ways, including diagnosis of pathogens that do not grow using conventional methods or grow very slowly, monitoring response to therapy, assessing risk of disease development, and determining disease prognosis. This section will review nucleic acid testing as it applies to specific pathogens with a focus on those pathogens for which nucleic acid testing is considered the standard of care.

Chlamydia Trachomatis and *Neisseria Gonorrhoeae*

CT and GC will be discussed together since several of the available nucleic acid tests for these pathogens are multiplex assays. Though both CT and GC can cause a variety of clinical infections, we will focus on genital infections.

Detection of CT is a challenging and important public health issue. CT is a major cause of genital infections, with an estimated 1 million cases occurring annually among sexually active adolescents and young adults in the United States.[67] More than half of the infections are asymptomatic.[167] Even when symptomatic, the diagnosis can be missed because the manifestations are protean. In males, CT infection may present as urethritis, epididymitis, prostatitis, or proctitis[24,124] and as cervicitis, endometritis, and urethritis in women, with 10% to 40% of infections in women progressing to pelvic inflammatory disease (PID) if untreated.[147,168] Related complications include chronic pelvic pain, ectopic pregnancies, and infertility. In the United States, CT infection is a likely cause of most secondary infertility in females. In pregnant women, there is the additional risk of transmitting the infection to the newborn during labor and delivery, leading to pneumonia or conjunctivitis in the newborn.

GC also may present in various ways, and the clinical presentations overlap those of CT. Males may have acute urethritis with discharge, epididymitis, prostatitis, and urethral strictures. In women, GC infection can produce cervicitis, which if left untreated can lead to PID, abscesses, or salpingitis.

The traditional methods for the diagnosis of CT infections include cell culture, immunofluorescent antigen detection, enzyme immunoassay, and more recently nonamplified nucleic acid detection. These traditional methods have been replaced in many laboratories with amplified nucleic acid tests because of their greater sensitivity in detecting CT from genital specimens. For GC, which was traditionally diagnosed based on culture methods that rely on selective media, nucleic acid testing does not offer a significant improvement in sensitivity compared with culture when culture is performed under ideal conditions. However, GC is a fastidious organism and is highly susceptible to extreme temperatures and desiccation, which can lead to a decreased sensitivity of culture, particularly when specimen transport is required

before culturing.[88] Nucleic acid testing for GC offers a sensitive and reliable alternative to culture.

In addition to a high sensitivity and specificity, nucleic acid testing offers several advantages over conventional culture and antigen-detection methods for the diagnosis of CT and GC. Testing for both pathogens can be done on a single specimen, and for some multiplex assays, testing is performed in a single reaction. Unlike the infectious organism itself, the DNA and RNA of GC and CT are quite stable in commercial transport devices, thus accounting for some of the increased sensitivity of these assays compared with the culture. The stability of nucleic acid avoids the necessity of immediate transport to the laboratory, and specimens may be stored refrigerated or at room temperature before transport. The transport and storage requirements vary among tests, so it is important to refer to the package insert for specific details. An additional advantage of nucleic acid testing is the use of urine specimens, which for women allows testing to be done without the need for a pelvic examination. In males, urine offers a convenient and sensitive alternative to collection with a urethral swab and increases the likelihood that asymptomatic males will agree to be tested.

FDA-cleared tests for the detection of CT and GC from clinical specimens (Table 42-4) can use a variety of specimens, including cervical swabs, urethral swabs, and urine from both asymptomatic and symptomatic individuals. Not all assays are approved for all conditions, and the current assays are not FDA-cleared for oral, rectal, respiratory, or conjunctival specimens. The performance characteristics of the assays vary (details are available in the package inserts); however, some general comments can be made concerning all of the tests. The diagnostic sensitivity of the tests varies depending on the specimen type and whether the patient is asymptomatic or symptomatic. Interpretation of the results of nucleic acid testing for CT can be challenging, because many studies have shown these assays to be more sensitive than culture, which was previously used as the gold standard for clinical trials. For males, the sensitivity of testing urine specimens is nearly equivalent to testing urethral swabs.[19,36,45,86,180] A limited volume (20 mL to 50 mL) of first-passed urine is preferred, as larger volumes will lead to a decreased concentration of organism in the sample and thus reduced sensitivity. With proper specimen collection, male urethral swabs and urine specimens have a sensitivity of nearly 100% for the detection of GC or CT. For women, cervical swab specimens provide the highest sensitivity for the detection of GC and CT, with many studies showing a sensitivity of 90% to 95%.[19,45,104,144,180] Urine specimens can be used, but they generally result in a lower sensitivity than cervical swabs (75% to 85%).[36,45,100,139] An alternative to urine testing in women is the use of self-collected vaginal swabs, which have shown in some studies a sensitivity that is equal to that obtained with cervical swabs, although use of this specimen type has not been cleared by the FDA.[80]

Nucleic acid testing is not the standard of care for diagnosing CT and GC in cases of sexual abuse.[33] Some have suggested its use in cases of sexual abuse of adults if testing is done using two assays, each of which targets a different region of the genome. This is not practical for clinical laboratories, because most use only one assay and no single transport medium can be used for all of the FDA-cleared CT and GC molecular assays. For cases of sexual abuse in chil-

TABLE 42-4 Summary of FDA-Cleared Testing for *Chlamydia Trachomatis* and *Neisseria Gonorrhoeae**

Test	Assay Method	Gene Target	Comments
Amplicor® CT/NG ***COBAS Amplicor® CT/NG*** (Roche Diagnostics, Indianapolis)	PCR	CT: cryptic plasmid NG: M-Ngo PII†	Internal control, multiplex assays
BD ProbeTec™ ET C. trachomatis and N. gonorrhoeae amplified DNA Assay (Becton-Dickinson, Franklin Lakes, NJ)	SDA	CT: cryptic plasmid NG: Piv_{Ng} gene	Internal control
Aptima Combo® 2 Assay‡ (GenProbe, San Diego, CA)	TMA	CT: 23S rRNA NG: 16S rRNA	Multiplex assay Target capture nucleic acid extraction
HC® 2 CT ID ***HC® 2 GC ID*** ***HC® 2 CT/GC Combo Test*** (Digene Corporation, Gaithersburg, MD)	Hybrid Capture	CT: cryptic plasmid GC: genomic DNA	

C. trachomatis and *CT, Chlamydia trachomatis; N. gonorrhoeae* and *GC, Neisseria gonorrhoeae; PCR,* polymerase chain reaction; *SDA,* strand displacement assay; *TMA,* transcription-mediated amplification.

*For FDA listings of these and any newer tests, see http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfRL/listing.cfm and use testcodes LSK and LSL for *Chlamydia* and *N. gonorrhea,* respectively.

†Cytosine DNA methyltransferase.

‡Confirmatory assays for CT and NG are also available.

dren, culture is still recommended for the detection of GC and CT. Another limitation of nucleic acid testing for the detection of CT or GC is use as a test of cure. Because DNA can persist in urine samples for up to 3 weeks after completion of therapy,[63] test of cure using nucleic acid testing is discouraged. If this must be done, then testing should be delayed for at least 3 weeks after initiating therapy.

For several of the GC assays, there is a reduced specificity because of cross-hybridization of primers with nongonococcal *Neisseria* species.[69,123] The ProbeTec test has been reported to produce false-positive results with *N. flavescens, N. lactamica, N. subflava,* and *N. cinerea,* and the Amplicor assay can produce false-positive results with *N. flavescens, N. lactamica,* and *N. sicca.* Because of cross-reactivity with these nongonococcal species of *Neisseria,* there is concern about generating false-positive results with pharyngeal specimens.[136] However, *N. cinerea, N. lactamica, N. subflava,* and *N. sicca* have also been isolated from genital mucosa, so it is also possible to generate false-positive results from genital specimens.

Other sources of false-positive results include carryover contamination of amplified product and cross-contamination during specimen collection, transport, or processing. Concerns over these issues have led to a discussion of confirmatory testing for CT and GC, since false-positive results can have psychosocial or medicolegal ramifications. False-positive results in a low-prevalence population can significantly reduce the predictive value of a positive result. For example, though the specificity of nucleic acid testing for GC or CT generally ranges from 98% to 99%, the positive predictive value may be as low as 60% to 70% in a population with a low prevalence. CDC Guidelines for STD testing[33] discuss options for confirmatory testing, including (1) testing of another specimen with a different assay that has a different target, (2) testing of the original specimen with a different assay that has a different target, (3) repeating the original test using the original specimen but with a blocking antibody or competitive probe, and (4) repeating the original test using original specimen. Confirmatory testing can be expensive and complicate work flow. Some laboratories have established gray zones or equivocal ranges for specimens with initial low-level positive results[46] and perform confirmatory testing only on such specimens. This appears to be a rational approach, since low-positive specimens are less likely to be confirmed as positive upon repeat testing—although other laboratories confirm all positive results, either using the same test or using a second assay.

False-negative results from inhibition of amplification are a consideration for both GC and CT testing and have been reported for both cervical swabs and urine specimens.[37,105,151] Inhibition rates may vary considerably depending on the amplification method and are related in part to the method used for nucleic acid extraction.[105] For tests that use a crude lysate in testing (such as the Amplicor and ProbeTec tests), inhibition rates tend to be higher than those seen with the Aptima combo test, which uses a target capture method to purify nucleic acid. For the assays that test a crude lysate, it is useful to include the internal control or amplification control to assess for inhibition of amplification. In this situation, the specimen would not be reported as negative for GC or CT unless there was amplification of the internal control. There are no clear guidelines concerning when it is appropriate to discontinue use of an internal control. However, to contain costs, some laboratories discontinue the use of the internal control if inhibition rates are less than 1%.

There is interest in performing CT and GC testing for liquid cytology specimens, because a single specimen can be used for cervical cytology (Pap smear) and for CT and GC testing.[10] The latter two tests would be performed on the liquid specimen that remained after completion of the Pap and HPV testing. However, there are several drawbacks to this approach that must be considered. The instruments used to prepare the liquid Pap smears were not designed to control for cross-contamination during processing, which may lead to false-positive results. CT and GC testing would not be performed until after the Pap smear results and HPV testing were complete, which could delay diagnosis and treatment of CT or GC infections. Moreover, there may be inadequate specimen remaining to complete CT and GC testing, thus requiring the patient to make a return visit to collect an additional sample. At this time it remains unclear how these various issues will be resolved.

Decisions regarding the choice of a specific amplification test for the detection of CT and GC should not be based solely on the cost of reagents. Other key factors to consider include test performance characteristics, such as diagnostic sensitivity and specificity, and whether the test has been cleared for urine and swab specimens in both symptomatic and asymptomatic individuals. Ideally the test should include an internal control, particularly if a crude lysate is used in the assay. Other factors to consider are degree of automation, ease of use, work flow issues, and space and equipment needs.

Human Papillomavirus

Anogenital HPV infections are common in both men and women. It is estimated that more than 24 million men and women in the United States are currently infected with HPV.[68] HPV is a sexually transmitted infection; it is most common among sexually active young women ages 15 through 25 years. In one study, cervicovaginal HPV was found in 43% of sexually active college women during a 3-year period.[78]

HPV is classified as either cutaneous or mucosal, infecting, respectively, keratinizing or nonkeratinizing epithelium. The focus of this section will be the mucosal types, which include approximately 30 types of HPV that infect the anogenital area. The types of HPV that are spread through sexual contact are classified as either low risk or high risk for progression to malignancy. There are multiple types of both low-risk and high-risk HPV. Infections with HPV can lead to a variety of outcomes, ranging from benign genital warts

to penile or cervical cancer. The outcome is driven by the type of HPV. Genital warts or condyloma acuminata are caused by low-risk HPV types and have a low likelihood of progressing to malignancy.[65] Conversely, penile cancer in men and cervical cancer in women are associated with high-risk HPV infections.[12,114,186,194] Infections can, however, be transient, and progression to cancer occurs over decades.[56,176]

Until recently, the standard method for the diagnosis of cervical cancer was the detection of abnormal cells by cervical cytology (Pap smear) or biopsy. The morphological changes associated with HPV infection include atypical squamous cells of undetermined significance (ASCUS), low-grade squamous intraepithelial lesion (LSIL), and high-grade squamous intraepithelial lesion (HSIL).[150,158] The diagnosis of ASCUS using a Pap smear has an estimated prevalence of 5% to 10%, with rates as high as 20% reported in sexually active women. Not all women with ASCUS progress to cervical cancer. HPV testing now plays an important role in assessing which women with ASCUS are at the highest risk of developing cervical cancer. Current recommendations are to test all women with ASCUS for the presence of high-risk HPV. Those women testing positive for high-risk HPV DNA should be referred for colposcopy, while those patients testing negative for HPV DNA can be followed according to routine practice.[164] Another more recently recognized use of high-risk HPV testing is as a primary screening tool for all women 30 years of age and older,[96] regardless of whether they have ASCUS detected on a Pap smear. This is based on the observation that women over the age of 30 who have persistent infection with high-risk types of HPV are at the greatest risk of developing cervical cancer. Women who have a normal Pap and a negative HPV screen are at very low risk of developing cervical cancer and would require less frequent screening than those with either an abnormal Pap or a positive HPV screen. Because of the clear association of HPV with cervical cancer and the availability of high-volume HPV testing, some are questioning the role of cervical cytology as a primary screen for cervical cancer.

Proper use of HPV testing requires not only detection of the virus or viral DNA, but also classifying it as either low-risk or high-risk. Viral culture for HPV is not easily performed and not available in clinical laboratories, and cytological examination cannot distinguish between low-risk and high-risk HPV infection. This has led laboratories to rely on molecular testing for the detection and classification of HPV. Various methods are available, including detection of HPV DNA by signal amplification and PCR. Currently the only available FDA-cleared test for the detection and classification of HPV DNA is the Hybrid Capture® 2 (HC2) test (Digene Corporation, Gaithersburg, Md.). The test relies on signal amplification technology and probe hybridization. The test uses two separate pools of RNA probes: one for detecting high-risk HPV DNA and another for low-risk HPV DNA. The high-risk pool contains RNA probes specific for HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68, and the low-risk pool of RNA probes detects HPV types 6, 11, 42, 43, and 44. The test results are reported as high-risk or low-risk HPV DNA detected. There is no identification of the specific high-risk type or low-risk type. PCR-based assays for the detection and typing of HPV are used in research laboratories[43,66,95,107,181]; however, PCR-based methods are in commercial development for use in the clinical laboratory.

The HC2 test has been FDA-cleared for three indications: aiding in the diagnosis of sexually transmitted HPV infections (high-risk and low-risk test), testing of specimens from patients with ASCUS-grade cytology results to determine the need for colposcopy (high-risk test only),[44] and primary screening of women age 30 and older (high-risk test only).[96] The recommended specimen types for HPV DNA testing include cervical swabs, liquid-based cytology specimens, and cervical biopsy specimens.

One concern with the HC2 test is difficulties with reproducibility of results near the signal/cutoff ratio for a positive result. Whether these signals are due to low concentrations of HPV DNA or they represent false-positive results remains unclear. As a result of this poor repeatability, some laboratories have established an equivocal range or gray zone for the test. When a result is within the gray zone, it is reported as indeterminate or testing is repeated and reported as positive only if a positive result is found on repeat testing. A potential cause of false-positive results for high-risk HPV is that certain low-risk HPVs are detected with the high-risk probe pool. Such false-positive results are seen in specimens with high concentrations of HPV 6 or HPV 42 DNA.

Testing of liquid-based cytology specimens in the HC2 assay is viewed favorably by many clinicians, since one specimen can be collected for both the Pap smear and HPV testing. Logistical issues with this approach can be challenging to the clinical laboratory. When Pap results are used to determine which samples are tested for HPV, the laboratory may find it difficult to complete the HPV testing within 21 days of specimen collection (as required according to the package insert) if there are delays in completing or reporting the Pap smear results. There may be inadequate volume of specimen remaining after the Pap smear is complete; this is a particular problem for specimens with a low cellular content, as a greater volume of specimen is used for the Pap smear. Finally, if the HC2 testing is not performed in the cytology laboratory, the testing laboratory may experience delays in specimen receipt, again making it difficult to complete testing within 21 days of specimen collection.

Several new approaches to HPV testing are under investigation that may provide more insight into identifying those women at highest risk of progressing to cervical cancer. These include assessing if there is prognostic value in determining HPV viral load and evaluating expression of HPV E6 and E7 mRNA as a marker for viral persistence and disease progression.

Human Immunodeficiency Virus Type 1

HIV-1, the causative agent of the acquired immunodeficiency syndrome (AIDS), is an RNA virus belonging to the genus lentivirus of the family Retroviridae. The replication of the virus is complex and involves reverse transcription of the RNA genome into a double-stranded DNA molecule, with subsequent integration into the host genome. The reverse transcriptase enzyme does not have proofreading capabilities, leading to the marked genetic diversity of HIV-1. There are two distinct genetic groups: the major (M) and outlier (O) groups. Viruses in the M group are further divided into 8 subtypes or clades, designated A through H, based on the sequence diversity within the HIV-1 *gag* and *env* genes.[41] Group M virus is found worldwide, with clade B predominating in Europe and North America. Complex replication cycles and genetic diversity are two factors that influence the design and interpretation of HIV-1 molecular assays.

Viral-Load Testing

The management of persons infected with human HIV-1 has been revolutionized by both viral-load and resistance testing. With these tools, it is possible to maximize the effectiveness of antiretroviral therapy for an individual. Viral-load testing became the standard of care around 1996, followed more recently by resistance testing. The clinical utility of viral-load testing (which refers to quantifying HIV-1 RNA, usually from plasma) has been well established. Testing is used to determine when to initiate antiretroviral therapy, to monitor response to therapy, and to predict time to progression to AIDS. Higher viral loads are associated with a more rapid progression to AIDS and death.[118,119,134] Viral-load testing is used more routinely in decisions regarding when to initiate antiretroviral therapy and in monitoring response to therapy. Current treatment guidelines[192] recommend initiating therapy for individuals based on several factors, including CD4 cell count, viral loads, and symptoms. In cases in which viral loads exceed 50,000 copies/mL, therapy can be initiated regardless of CD4 cell count and the presence of symptoms.

The current standard for treating HIV-1–infected individuals is to use combinations of protease inhibitors or non-nucleoside reverse-transcriptase inhibitors with nucleoside analogs.[192] This combination therapy is often referred to as highly active antiretroviral therapy or HAART. Initial use of these effective drug combinations in individuals who have not been treated with them before ("naïve" individuals) is expected to decrease viral-load values by at least $2 \log_{10}$ copies/mL. The goal of therapy is to achieve viral-load values below the limit of detection of currently available assays (50 copies/mL), although this is not always possible in all individuals, particularly in those with very high pretreatment viral-load values or in those who have failed in prior therapeutic regimens. Guidelines for the use of HIV-1 RNA concentrations in clinical practice have been published,[156] and are frequently updated (http://www.aidsinfo.nih.gov/, http://www.iasusa.org). In general, a plasma HIV-1 viral load should be measured before beginning therapy (baseline) and then again at 2 to 8 weeks after the initiation of therapy to determine the response to therapy. Testing is then repeated at 3- to 4-month intervals to evaluate continued effectiveness of the regimen. Any increase in viral load should be confirmed with repeat testing, as a variety of other illnesses can transiently increase viral load. When a significant increase in viral load has been documented, HIV-1 resistance testing should be considered (see below).

Molecular assays are also useful in the diagnosis of acute HIV-1 infection in neonates because maternal IgG crosses the placenta, an uninfected newborn may be seropositive into the second year of life. Both qualitative proviral DNA tests and viral-load assays are useful for the diagnosis of HIV-1 infection in newborns.[47,170,193] HIV-1 RNA testing appears to be more sensitive than proviral DNA testing for the diagnosis of acute HIV-1 infection in newborns,[47,170] though both are used in clinical practice. The diagnosis of HIV-1 infection in a newborn requires testing at two different time points, usually shortly after birth and then again at 6 weeks to several months of age.

The use of HIV-1 viral-load testing for *diagnosing* acute HIV-1 infection in adults is more controversial. The currently available viral-load assays are approved only for use in patients known to be infected with HIV-1, but they have clear utility in the diagnosis of acute infection, which is defined as the period after exposure to the virus but before seroconversion. In the "window period," the ELISA and Western blot assays are negative or indeterminate, so additional testing is necessary. Individuals with acute infection are often symptomatic with a mononucleosis type of syndrome, which may include fever, fatigue, rash, lymphadenopathy, and oral ulcers.[89] During this acute infection, the plasma concentration of viral RNA is very high, usually 10^5 to 10^7 copies/mL, and viral-load measurements are a useful diagnostic tool. Acute HIV-1 infection should be suspected in an individual presenting with appropriate symptoms and risk factors. In these individuals, testing for acute HIV-1 infection would include an enzyme-linked immunosorbent assay (ELISA) and a viral-load assay. Care must be taken to correctly interpret these test results, as individuals with acute HIV-1 infection would be expected to have a negative or indeterminate ELISA and/or Western blot, and a very high viral load (greater than 100,000 copies/mL). The concern with using viral-load testing to diagnose acute HIV infection is that false-positive results have been reported.[48] In one study the false-positive results were found when using the Versant bDNA test,[48] with false-positive results usually lower than 2000 copies/mL. Before diagnosing acute HIV infection, individuals must be educated regarding the limitations of these tests and must give informed consent to testing. To minimize the likelihood of reporting a false-positive result, repeat testing should be done on all specimens with a detectable viral load and an HIV1/2 ELISA should be obtained at the time of viral-load testing. It is critical to

TABLE 42-5 The First Quantitative HIV (Viral Load) Assays Approved by the FDA*

Test	Amplification Method	Reportable Range
Amplicor HIV Monitor v1.5 Test (Roche Diagnostics, Indianapolis, IN)	RT-PCR	Ultrasensitive: 50-100,000 copies/mL Standard: 400-750,000 copies/mL
Versant HIV-1 RNA 3.0 Assay (Bayer Diagnostics, Tarrytown, NY)	bDNA	75-500,000 copies/mL
NucliSens HIV-1 QT Assay (bioMerieux, Durham, NC)	NASBA	176-3,470,000 copies/mL

RT-PCR, Reverse transcription-polymerase chain reaction; *bDNA,* branched DNA; *NASBA,* nucleic acid sequence based amplification.
*For FDA listings of these and any newer tests, visit http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfRL/listing.cfm and use test code MTL.

remember that patients with acute retroviral syndrome should have very high concentrations of HIV-1 RNA.

HIV-1 viral-load assays that are currently FDA-approved are listed in Table 42-5. The lower limit of quantification differs among the three assays. The reportable concentration range of each of the Amplicor assays is limited, so both an ultrasensitive and a standard version of the test are needed to cover the clinically important range of viral-load values. Viral-load assays must be able to accurately quantify the various viral subtypes. In the United States and Europe subtype B predominates, though infections with non-B subtypes are becoming more common and are certainly an important cause of HIV-1 infection globally. The Versant bDNA assay will accurately quantify HIV-1 subtypes A thru G,[85] and the Amplicor RT-PCR version 1.5 will accurately quantify subtypes A through H.[85,137,138] The earlier Amplicor assay (version 1.0) underquantified non-B subtypes[85] and has been replaced by the 1.5 assay version. The NucliSens NASBA assay underestimates concentrations of subtype G.[85,130,137] None of the currently available assays is recommended for the quantification of group O virus. Viral-load values obtained with the different assays may not always agree, so it is recommended to choose one assay when monitoring patients over time.

The available viral-load assays have an intraassay imprecision (CV) of 0.12 to 0.2 $\log_{10}$, with the Versant bDNA assay showing the best precision.[16] For the Amplicor (version 1.0) assay, the total variation was approximately 0.26 $\log_{10}$, including intraassay, interassay, and biological variation.[17] Based on this degree of variation, changes in viral load should exceed 0.5 $\log_{10}$ (threefold) to represent a biologically relevant change in viral replication. Reporting viral-load results as $\log_{10}$ copies/mL is recommended[127] and will assist in preventing clinicians from overinterpreting small changes in viral load. This is particularly important for values near the limit of quantification, where assay variability is the greatest. A variety of acute and opportunistic infections and vaccinations can transiently increase HIV-1 RNA in plasma,[53,134,169] so it is recommended not to measure viral load for monitoring of individuals who are acutely ill and those who have been recently vaccinated.

Viral-load testing is routinely performed on plasma specimens, and ethylene diamine tetraacetic acid (EDTA) is the anticoagulant of choice. Acid citrate dextrose is also an acceptable anticoagulant, but for the Amplicor and Versant assays blood anticoagulated in heparin is unacceptable. Viral-load testing can be done on specimens other than plasma, including serum, dried blood (or plasma) spots on filter paper, CSF, and genital secretions. The assays have not been validated on all of these specimen types, and testing these specimens is usually reserved for research studies. It is critical to handle clinical specimens properly to minimize the risk of RNA degradation during specimen collection and transport. Plasma should be separated within 6 hours of collection, and ideally stored at −20 °C, although plasma viral RNA is stable at 4 °C for several days. For laboratories performing testing from specimens collected at remote sites, VACUTAINER Plasma Preparation Tubes (PPTs) can be useful. The tube can be centrifuged at the collection site and shipped in the PPT tube. A gel provides a physical barrier between the plasma and cells, and tubes can be shipped without the need to transfer the plasma into a separate tube.[79]

Resistance Testing

Four general classes of antiretroviral drugs are used in clinical care: nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and a new class of drug, fusion inhibitors. Viral resistance can occur with each of these classes of drug, particularly when viral replication is not maximally suppressed during therapy. The current standard of care is to use regimens that contain a combination of drugs, usually a PI or NNRTIs with several NRTIs, since resistance is less likely to occur on the complex regimens than on monotherapy.[192]

A variety of studies have evaluated the clinical utility of antiviral resistance testing in HIV-1 infected individuals. Several early prospective randomized clinical trials of genotypical resistance testing were conducted with persons who had failed therapy with multidrug regimens, including the protease inhibitors and NRTIs. In both the VIRADAPT[39,54] and GART[8] studies, the selection of the salvage regimen was

determined either by the use of genotypical resistance testing (genotype arm) or by considering which antiretroviral drugs had been used in prior treatment regimens (control arm). The response rates in the genotype arms were higher than in the control arm. For example, in the VIRADAPT study, patients in the genotype arm had a greater decrease in viral load 6 months after initiating salvage therapy, and more of them (32% versus 14%) had plasma viral loads <200 copies/mL.[39,54] The Havana trial helped establish the utility of expert advice in interpreting the genotypical resistance data by comparing genotype resistance testing, expert advice, or both with the standard of care for selecting a regimen in patients failing therapy.[179] Although either genotyping or expert advice improved response compared with the control group, the best response was seen in the group receiving both genotyping and expert advice. The VIRA3001 study, a prospective randomized trial that compared standard of care to phenotypic resistance testing in patients who failed a PI-containing regimen, found a better virological outcome for patients in the phenotypic arm.[40] Although some trials of resistance testing have not shown improved clinical outcomes compared with standard of care,[72,120,122] the results of the randomized trials favor use of resistance testing.

Guidelines for the appropriate use of HIV-1 resistance testing in adults have been established by an International AIDS Society-USA panel of experts.[76] Resistance testing is recommended in patients who are failing on an initial antiretroviral regimen and in those failing after numerous regimens. In addition, resistance testing is recommended before initiating therapy for patients who have been infected within the previous 2 years. This is based on the finding that some resistance mutations can persist in plasma HIV-1 RNA for more than 12 months in untreated patients.[18] Resistance testing is also recommended in pregnant women to optimize treatment and in hopes of minimizing transmission of HIV-1 infection to the neonate. As it is possible to transmit drug-resistant virus, it is also recommended that resistance testing be done on patients presenting with acute or recent (within 12 months) HIV-1 infection, particularly if the person from whom HIV-1 was acquired ("source patient") is known and is receiving antiretroviral therapy.

Genotypic assays identify specific mutations or nucleotide changes that are associated with a decreased susceptibility to an antiviral drug. The effective use of genotypic resistance testing requires an extensive understanding of the genetics of antiretroviral resistance. There are several methods available for genotypic assays, including automated dideoxynucleoside terminator cycle sequencing, DNA hybridization using high-density microarrays, and reverse hybridization using the line probe assay. This discussion will be limited to automated sequencing methods, since this is the method used in the overwhelming majority of genotypic resistance testing performed for management of patients. The currently available assays will detect mutations in the reverse transcriptase and protease gene; modifications of existing assays will be needed to detect the resistance mutations associated with fusion inhibitors.

The initial step in genotypic assays is the isolation of HIV-1 RNA from plasma, followed by RT-PCR amplification and sequencing of the reverse transcriptase and protease genes. The analysis of the results involves sequence alignment and editing, mutation identification by comparison with a wild-type sequence, and interpretation of the clinical significance of the mutations identified. Most clinical laboratories performing genotypic resistance testing rely on commercial assays that provide reagents and software programs to assist with the interpretation of the results. Two assays have been cleared by the FDA, the Trugene HIV-1 Genotyping Kit and OpenGene DNA Sequencing System (Bayer Diagnostics Corp., Tarrytown, N.Y.) and the ViroSeq HIV-1 Genotyping System (Celera Diagnostics/Abbott Laboratories, Abbott Park, Ill.). In addition to these commercial assays, several laboratories have developed automated-cycle sequencing assays for HIV-1 resistance testing.

The interpretation of genotypic resistance testing is complex. The interpretation of resistance mutations uses "rules-based" software that takes into account cross-resistance and interactions of mutations. The commercially available systems generate a summary report that lists the various mutations that have been identified in the reverse transcriptase and protease genes, and each drug is reported as resistant, possibly resistant, no evidence of resistance, or insufficient evidence. A comprehensive discussion of the specific mutations associated with each antiretroviral drug and the interactions of mutations is beyond the scope of this chapter, but is available from a variety of sources[76,122] (http://hiv-web.lanl.gov/content/index, http://www.iasusa.org., http://hivdb.standford.edu/).

Phenotypic resistance assays measure viral replication in the presence of antiretroviral drugs. Results of phenotypic assays are typically reported as the inhibitory concentration of a drug that reduces in vitro HIV-1 replication by 50% (IC_{50}). The IC_{50} is usually reported as the fold change in IC_{50} relative to a wild-type strain. Initially, phenotypic assays required the isolation of infectious HIV-1 from a blood specimen. Newer phenotypic assays use high-throughput automated assays based on recombinant DNA technology. For these assays, HIV-1 RNA is amplified from a plasma specimen, eliminating the need for a viral isolate. This testing is not performed in clinical laboratories and the technology is available only from two commercial laboratories. For the PhenoSense assay (ViroLogic, San Francisco, Calif.), the protease and reverse transcriptase genes are amplified using RT-PCR and inserted into a modified HIV-1 vector that has a luciferase reporter-gene in place of the viral envelope gene.[140] Viral replication is measured by quantification of luciferase expression in the presence of various concentrations of antiretroviral drugs. The reproducibility of the assay is such that increases in IC_{50} of greater than 2.5-fold can be reliably detected in the assay. The other assay (Antivirogram, Virco, Mechelen, Belgium) combines patient and HIV-1

vector sequences using in vitro recombination.[75] Viral replication is measured using a reporter-gene system. Based on replicate studies performed by the company, reduced susceptibility is defined as a greater than fourfold increase in IC_{50} compared with the wild-type virus. This technical cutoff often differs from the cutoff that is associated with clinical resistance to a drug, which is referred to as the clinical cutoff. The change in IC_{50} associated with clinical failure may differ for each drug tested. For example, with the protease inhibitor lopinavir, the IC_{50} that correlates with clinical resistance may be in the range of a greater than or equal to a tenfold increase in IC_{50},[184] compared with a twofold increase for the NRTI ddI. It is likely that IC_{50} cutoffs will continue to be modified as more clinical outcomes data become available. Results of phenotypic assays include not only the change in IC_{50} value, but also an interpretation of whether there is an increase or decrease in susceptibility compared with the wild-type virus.

A "virtual phenotype" is also available commercially for assessing HIV-1 drug resistance. With a virtual phenotype, rather than performing a phenotypic assay directly, the information is inferred from the genotypic assay. The results of the genotypic assay are entered into a database containing matching genotypic and phenotypic results from thousands of clinical specimens, and the closest matching phenotypic results are averaged and reported as the virtual phenotype.

Both phenotypic and genotypic assays are used in clinical care: some clinicians prefer phenotypic testing because it is a direct measure of viral susceptibility, while others prefer genotypic testing because the development of a mutation may precede phenotypic expression of resistance.[77] Other advantages of genotypic testing include relatively rapid turnaround time (a few days), easier availability, and lower cost than phenotypic testing. Providers often use genotypic testing routinely and rely on phenotypic testing for patients who have failed multiple regimens and have very complex genotypic results. If both assays are used, it is key to remember that the results of the two assays may not agree, because the presence of a resistance mutation does not assure its expression in a phenotypic assay.

A limitation of the currently used genotypic and phenotypic assays is that they can detect only those mutants that make up at least 20% of the total viral population. Regimens chosen based on resistance testing may not always be effective because the minority populations will quickly predominate in the presence of a drug. Drug selection pressure is also needed for some resistance mutations to persist at detectable concentrations in the viral population; when the drug therapy is discontinued, the wild-type virus may quickly predominate. For this reason, it is recommended that specimens for resistance testing be obtained while the patient is on antiretroviral therapy.

The minimum viral load required for reliable resistance testing is approximately 1000 copies/mL. Because genotyping assays are especially sensitive to RNA degradation, care must be taken to properly handle the specimen after collection. Guidelines outlined for collection and transport of specimens for testing in viral-load assays should be followed for resistance testing.

Herpes Simplex Virus

HSV, a member of the herpesvirus family, is a double-stranded DNA virus. Following primary infection, the virus remains latent in sensory neurons and can be reactivated under a variety of situations, including stress, trauma, sun exposure, and various immunocompromised states. HSV types 1 and 2 produce various clinical syndromes involving the skin, eye, central nervous system (CNS), and genital tract. Although nucleic acid testing has been used to detect HSV DNA in all of these clinical manifestations, this discussion will focus on the use of HSV PCR for the diagnosis of CNS infections, since nucleic acid amplification testing is widely viewed as the standard of care for the diagnosis of these infections.

HSV causes both encephalitis and meningitis; in adults encephalitis is usually caused by infection with HSV type 1, and meningitis is most commonly caused by HSV type 2. HSV encephalitis is a severe infection with a high morbidity and mortality; treatment with acyclovir reduces the mortality from approximately 70% in untreated infections to 19% to 28%. Neurological impairment, however, is common (about 50%) in those who survive.[188,189] HSV encephalitis may reflect primary infection or reactivation of latent infection. HSV meningitis is usually a self-limited disease, which resolves during the course of several days without therapy. In some patients the disease may recur as a lymphocytic meningitis over a period of years.[178,188]

Neonatal HSV infection occurs in 1:3500 to 1:5000 deliveries in the United States.[188] It is most commonly acquired by intrapartum contact with infected maternal genital secretions and is usually caused by HSV type 2. In the newborn there are three general presentations of the disease: skin, eye, and mouth disease accounts for approximately 45% of infections, encephalitis accounts for 35%, and disseminated disease accounts for 20%. As disseminated disease is often associated with neurological disease, CNS disease occurs in about 50% of newborns with neonatal HSV infection.

HSV encephalitis cannot be distinguished clinically from encephalitis caused by other viruses such as West Nile virus, St. Louis encephalitis virus, and Eastern equine encephalitis virus. Historically the gold standard for the diagnosis of HSV encephalitis required brain biopsy with identification of HSV by cell culture or immunohistochemical staining. This approach provided high sensitivity (99%) and specificity (100%), but it required an invasive procedure, and several days elapsed before results were available. Cell culture of CSF has a sensitivity of less than 10% for the diagnosis of HSV encephalitis in adults. Tests that measure HSV antigen or antibody in CSF have sensitivities of 75% to 85%, and specificities of 60% to 90%.[188] Because of the limitations of conventional methods, there was interest in assessing the

clinical utility of PCR for the detection of HSV DNA from the CSF of patients with encephalitis.

The two largest studies have compared HSV PCR on CSF specimens with a brain biopsy[6,97] in patients with suspected HSV encephalitis. The sensitivity and specificity of PCR were greater than 95%, and the sensitivity of HSV PCR did not decrease significantly until 5 to 7 days after start of therapy. PCR is positive early in the course of illness, usually within the first 24 hours of symptoms, and in some individuals HSV DNA can persist in the CSF for weeks after initiating therapy.[6,97,190]

The clinical utility of HSV PCR has also been established for the diagnosis of neonatal HSV infection. In one study,[92] HSV DNA was detected in the CSF of 76% (26 of 34) infants with CNS disease, 94% (13 of 14) with disseminated infection, and 24% (7 of 29) with skin, eye, or mouth disease. The persistence of HSV DNA in the CSF of newborns for greater than 1 week after initiating therapy is associated with a poor outcome.[106] Based on the findings, detection of HSV DNA in CSF by PCR has become the standard of care for the diagnosis of HSV encephalitis and neonatal HSV infection. In newborns with disseminated disease, HSV DNA may be detected in serum or plasma specimens, and can be a useful diagnostic tool in newborns if it is not possible to do a lumbar puncture. Though the sensitivity of HSV PCR is high, it is not 100%, so a negative PCR test may not rule out neurological disease HSV as the cause, particularly if the pretest probability is high. In this situation it is important to consider repeat testing.

As with HSV encephalitis, HSV meningitis cannot be distinguished clinically from other viral meningitides, although recurrence of viral meningitis is a strong clue that HSV may be the etiologic agent. Unlike HSV encephalitis, HSV meningitis has not been the subject of large studies evaluating the clinical utility of PCR for diagnosis. Nonetheless, as the sensitivity of cell culture of CSF specimens is only 50%, HSV PCR of CSF is commonly used in the evaluation of meningitis. It has been described as accurate in anecdotal reports.[159,178]

Currently there are no FDA-cleared assays for the detection of HSV DNA from clinical specimens, and the performance characteristics of existing assays may vary. The Light Cycler assay (Roche Diagnostics, Indianapolis, IN) is available as an analyte-specific reagent PCR assay designed for the detection of HSV DNA types 1 and 2 equally. Distinguishing between HSV types 1 and 2 may not be necessary, since the clinical management is the same for both infections. Primers used for the detection of HSV DNA commonly target the polymerase, glycoprotein B, glycoprotein D, or thymidine kinase genes. It is important that the primers not amplify DNA from other herpesviruses that are associated with neurological disease; these include cytomegalovirus, varicella zoster virus, human herpesvirus type 6, and Epstein-Barr virus.

HSV PCR assays need low detection limits (several hundred copies per milliliter of specimen) to be useful in evaluation of neurological disease. This is particularly true for the diagnosis of meningitis in which CSF concentrations of DNA tend to be lower than those seen with encephalitis. HSV neurological disease rarely occurs without an increased CSF white blood cell count or protein concentration.[162] Caution should be exercised in applying this generalization to immunocompromised individuals, as they may not mount a typical inflammatory response to HSV infection. Although HSV PCR of CSF specimens is clearly the gold standard for the diagnosis of neurological disease, results should be interpreted with caution since neither sensitivity nor specificity is 100%. Test results should always be interpreted within the context of the clinical presentation of the patient. If results do not correlate with the clinical impression, repeat testing should be performed.

Enterovirus

Enteroviruses are a diverse group of single-stranded RNA viruses belonging to the Picornavirus family. The group includes polioviruses, enteroviruses types A-D, and parechovirus (human echovirus). Numerous clinical presentations are seen with the nonpolioviruses, including acute aseptic meningitis, encephalitis, exanthems, conjunctivitis, acute respiratory disease, gastrointestinal disease, myopericarditis, and sepsislike syndrome in neonates. Diagnoses typically are based on clinical presentation and/or culture methods. Cell culture methods have several drawbacks, including the requirement to inoculate multiple cell lines, because no single cell line is optimal for all enterovirus types; the inability to grow some enterovirus types in cell culture; the limited diagnostic sensitivity of cell culture (65% to 75%); and the long turnaround time of 3 to 8 days for those enteroviruses that do grow in a cell culture.[38] The long turnaround time for the culture means that results are rarely available in a timeframe to influence clinical management. Nucleic acid testing offers several important advantages over cell culture, including improved sensitivity and turnaround time. As a result, nucleic acid testing is considered the new gold standard for the diagnosis of aseptic meningitis and neonatal sepsis syndrome caused by the enterovirus.

Two methods are used for the detection of enteroviral RNA from clinical specimens: RT-PCR and NASBA. The primers used in clinical testing most commonly target the highly conserved 5′-untranslated region of the gene (5′UTR)[152,154] and will detect polioviruses and enteroviruses. These primers will not detect echovirus types 22 and 23, which have been reclassified as parechoviruses, although these viruses can cause aseptic meningitis. In general, molecular assays have good detection limits ranging from 0.1 to 50 tissue culture infectious doses 50 (TCID50) per assay.* The assays are quite specific, but sequence similarities may allow amplification of some types of rhinoviruses.[13,185,196] As with HSV, there is no FDA-cleared assay for the detection of

*References 13, 61, 133, 145, 152, 171, 185, 196, 197.

enterovirus RNA from clinical specimens. Several ASRs are available for detection of enterovirus RNA from CSF specimens to assist laboratorians in assay development. The Enterovirus Consensus assay (Argene Biosoft, Varihles, France) uses RT-PCR technology and detects all 64 enteroviral serotypes.[13] The other available ASR assay is the NucliSens Basic Kit (bioMerieux, Boxtel, the Netherlands), which uses NASBA technology.[61,196] A clinical evaluation of the NASBA assay showed it to be more sensitive than CSF viral culture for the detection of enterovirus, and its had a specificity of 100%.[196]

The clinical utility of nucleic acid testing for the diagnosis of enteroviral infections has been documented in a variety of clinical studies,[1,2,91] with the testing showing a sensitivity equal to or greater than that of cell culture, a high specificity, and faster turnaround time than cell culture. Several studies have suggested that the introduction of molecular methods for the diagnosis of enteroviral infections in infants and pediatric patients can lead to cost savings in other parts of the hospital because of the decreased length of stay, reduction in the use of antibiotics, and reduction in imaging studies.[71,108,128,145] The cost savings may be small, however, as the typical length of stay for children with viral meningitis is short with or without use of molecular testing (personal communication, D.E. Bruns, 22 May 2004). To maximize the benefit to patient care and cost savings, testing should be available daily.

As mentioned above, many molecular assays detect rhinoviruses and most will detect polioviruses. These two factors can lead to unexpected and misleading positive results when testing respiratory or stool specimens. The diagnosis of enterovirus meningitis should be based on testing of CSF specimens, while sepsis syndrome in the neonate is best made by testing serum, plasma, or CSF samples.

Perinatal Group B Streptococcal Disease

In the 1970s Group B streptococcal (GBS) disease was the leading infectious cause of neonatal morbidity and mortality, with case rates of 2 to 3 per 1000 live births and case-fatality rates as high as 50%.[31] In 1996, consensus guidelines from the CDC, the American Academy of Pediatrics, and the American College of Obstetrics and Gynecology were issued in an effort to reduce the rate of GBS disease in newborns.[31] The guidelines called for use of intrapartum prophylactic antibiotics for GBS using either a risk-based or screening-based approach. In the risk-based approach, antibiotics were administered based on the identification of one of the following risk factors: intrapartum fever, prolonged rupture of membranes, or imminent preterm delivery. For the screening-based approach, vaginal and/or rectal cultures were collected at 35 to 37 weeks of gestation, and those women with positive cultures received intrapartum antibiotics. Since the widespread implementation of these guidelines, the number of cases of GBS disease has decreased, but GBS remains a serious cause of neonatal infection. GBS disease in the newborn is classified as either early disease, which occurs within 1 week of life and usually presents as a sepsis syndrome or pneumonia, or late disease, which is defined as that presenting at greater than 1 week of life and that presents most commonly as sepsis or meningitis.

GBS colonization of pregnant women is common, with a prevalence of 10% to 30%; colonization may be transient, chronic, or intermittent.[148] Those women who are colonized are 25 times more likely to deliver infants with early onset GBS disease.[14] The effectiveness of the 1996 guidelines for the prevention of neonatal GBS was recently reevaluated, and it was determined that the screening approach to GBS prevention was greater than 50% more effective than the risk-based approach.[160] Based on these findings, in 2002 the CDC issued updated guidelines recommending that vaginal/rectal GBS screening cultures be done on all pregnant women. The exceptions included women with a previous infant that had GBS disease or those with GBS bacteriuria during pregnancy, because these women require intrapartum antibiotics. The risk-based approach is to be used only for women with unknown GBS status at the time of labor and delivery. See the CDC guidelines[31] for a more detailed description, and refer to the CDC Web site for updates.

Methods for GBS screening cultures have been standardized and include collection of a vaginal/rectal swab and transport to the laboratory in either Aimes or Stuarts media. The specimen is then inoculated into an enrichment broth (LIM broth), incubated for 18 to 24 hours, and then subcultured onto a sheep-blood agar plate. GBS is then identified based on colony morphology, hemolysis, and latex agglutination testing. This two-step method ensures maximal sensitivity for GBD detection. GBS cultures usually require 2 to 3 days to complete. Since GBS is universally susceptible to penicillin and ampicillin, antimicrobial susceptibility testing is not routinely performed, but is needed for women with a serious allergy to penicillin.

A recent study evaluated the clinical utility of using a real-time PCR assay for the detection of GBS in pregnant women.[9] A Light Cycler assay (Roche Diagnostics, Indianapolis, IN) was compared with cultures in 112 pregnant women and was found to have a sensitivity of 97%, a specificity of 100%, and a negative and positive predictive value of 98.8% and 100%, respectively. Testing results were available within 45 minutes of the time the specimen arrived in the laboratory, which raised the possibility of offering real-time testing to women who present in labor. This could be especially useful for women who present with an unknown GBS status; based on current guidelines, these women would receive intrapartum antibiotics based on risk factors. As women without risk factors are still at risk of delivering newborns with GBS disease,[160] PCR testing would undoubtedly offer a more sensitive method for GBS detection than one based on risk factors alone. In addition, intrapartum testing

would be useful in identifying women whose GBS status changes in the interval between screening culture (week 35 to 37 of gestation) and the time of delivery.

Recently a real-time PCR assay was cleared by the FDA (IDI-Strep B using the Cepheid Smart Cycler, Infection Diagnostic Inc., Quebec) for the detection of GBS from vaginal and/or rectal swabs in pregnant women. In a multicenter clinical trial, the IDI-Strep B test demonstrated a sensitivity of 94% and a specificity of 96% compared with intrapartum culture (IDI-Strep B package insert). The assay requires a few simple hands-on steps to prepare the specimen. The testing cartridge is then inserted into the Smart Cycler, and testing is complete in less than 1 hour. The test also includes an internal control to monitor for inhibition of amplification. The IDI-Strep B test offers a rapid and sensitive alternative to GBS culture. These advantages need to be balanced with the challenge of providing intrapartum test results to clinicians within 1 to 2 hours at any time of day or night, and the cost of nucleic acid testing must be compared with the cost of culture. If intrapartum testing is done, there will not be adequate time for erythromycin and clindamycin susceptibility testing, so women with severe penicillin allergies will require therapy with vancomycin. An alternative approach is to replace antepartum culture at 35 to 37 weeks of gestation with the real-time PCR assay. With the availability of an FDA-cleared test, there will be more discussion on the use of GBS PCR testing of pregnant women.

Cytomegalovirus

CMV, a member of the herpesvirus family, is a double-stranded enveloped DNA virus. CMV causes a clinically minor infection in immunocompetent individuals, but remains an important pathogen in immunocompromised individuals, including persons with AIDS, transplant recipients, and those on immune-modulating drugs. Primary infection is usually asymptomatic in immunocompetent persons, though a small percentage of individuals with CMV infection may develop a mononucleosis type of syndrome. Following the primary infection, a lifelong latent infection is established, which does not cause clinical symptoms. However, if an infected individual becomes immunocompromised, the virus can reactivate, leading to a wide variety of clinical syndromes.

The most severe CMV infections are seen in those individuals who acquire their primary infection while immunocompromised. In persons with AIDS, CMV disease rarely occurs when the CD4+ cell count is above 100 cells/mm^3; the most common clinical presentations are retinitis, esophagitis, and colitis. In transplant recipients, the occurrence and severity of CMV disease are related to the CMV serostatus of the organ donor and recipient, the type of organ transplanted, and the overall degree of immunosuppression. For example, CMV disease tends to be more severe in lung transplant recipients than in renal transplant recipients. For all types of organ recipients, the most severe disease occurs when CMV-seronegative recipients receive an organ from a CMV-seropositive donor, and the primary CMV infection occurs while the person is immunosuppressed. CMV disease can also occur in seropositive individuals whether they receive an organ from a seropositive or seronegative donor. The clinical findings associated with CMV disease in transplant recipients are diverse and include interstitial pneumonitis, esophagitis and colitis, fever, leukopenia, and less commonly retinitis and encephalitis. CMV disease also occurs in bone marrow transplant recipients.

The diagnosis of CMV disease represents a challenge because of the presence of the latent infection. Immunocompromised individuals can have an asymptomatic, clinically insignificant, low-level, persistent infection that must be distinguished from clinically important active CMV disease. The distinction can be challenging when using sensitive molecular assays that can detect small amounts of CMV DNA in clinical specimens.

Traditionally the diagnosis of CMV disease relied on the detection of CMV from clinical specimens by use of cell culture techniques in human diploid fibroblasts. Though considered the gold standard, these conventional culture methods are labor-intensive and have a long turnaround time of 1 to 3 weeks. In addition, the assays lack adequate sensitivity for detecting CMV present in blood specimens.[112,113] The rapid shell-vial culture method can provide results in 1 to 2 days and is useful for detection of CMV in tissue, respiratory, and urine specimens. However, this assay may also fail to detect CMV in blood.[112,113] Many laboratories rely on the antigenemia assay, which detects the matrix protein pp65 in polymorphonuclear cells. This semiquantitative assay is rapid, and the number of CMV antigen-positive cells correlates with the likelihood of CMV disease,[113,187] but the assay is labor-intensive, and CMV antigen is not stable in whole blood specimens for periods of greater than 24 hours.

In light of the limitations of culture and antigen detection methods, there has been great interest in using nucleic acid testing for the detection and quantification of CMV DNA from plasma and blood specimens. Qualitative and quantitative molecular assays available for this purpose are outlined in Table 42-6. The two qualitative assays that have been cleared by the FDA for detection of CMV from blood specimens are the Hybrid Capture System CMV DNA test (version 2) (Digene Corp., Gaithersburg, Md.) and the NucliSens CMV test (bioMerieux, Durham, N.C.). The Hybrid Capture assay is a signal-amplification assay that detects CMV DNA in whole blood specimens. The NucliSens assay uses NASBA technology to detect pp67 late messenger RNA in whole blood specimens. The isothermal NASBA assay detects pp67 RNA but not CMV DNA, eliminating concerns about detection of DNA in latent infection. Quantitative molecular CMV assays that are available include the Hybrid Capture assay mentioned above and the Amplicor CMV MONITOR test (Roche Diagnostics, Indianapolis), a

TABLE 42-6 CMV Tests in Clinical Use*

Test	Amplification Method	Range
Hybrid Capture System CMV DNA (version 2) (Digene Corp, Gaithersburg, Md)	Signal amplification	1400-600,000 copies/mL
Amplicor CMV Monitor Test (Roche Diagnostics, Indianapolis, IN)	PCR	400-50,000 copies/mL
NucliSens CMV Test (bioMerieux, Durham, NC)	NASBA	Qualitative
Laboratory Developed Test	PCR	Varies

RT-PCR, Reverse transcription-polymerase chain reaction; *NASBA*, nucleic acid sequence based amplification.

DNA PCR assay (neither of which has been cleared by the FDA). CMV PCR LDTs that use standard and real-time PCR methods are also widely used in clinical laboratories. These LDTs use various specimen types, nucleic acid extraction methods, target genes, calibrators, and detection methods. As a result, viral load values obtained with the different assays may not always agree. This makes it very difficult to compare results among clinical studies that use these assays and to establish concentrations of CMV DNA that correlate with clinical disease.

The analytical performances have been evaluated for the Amplicor PCR and Hybrid Capture assays. The imprecision (expressed as standard deviations) of the assays ranges from 0.11 to 0.48 $\log_{10}$, with greater variability seen below 1000 copies/mL (3.0 $\log_{10}$ copies/mL).[25,28] In general the Amplicor assay is more reproducible than the Hybrid Capture assay.[28] Based on these data, changes in viral load (copies per milliliter) less than threefold to fivefold may not represent clinically relevant changes in viral replication.

An unsettled issue for CMV molecular assays is the appropriate specimen type for testing. Almost all assays use either plasma or whole blood, with concentrations of CMV DNA measured in whole blood higher than those measured in plasma.[146] Because pp67 RNA is intracellular, the NucliSens assay uses whole blood samples. Likewise the Hybrid Capture assay has been designed to measure CMV DNA in whole blood specimens. The Amplicor PCR assay can accommodate blood or plasma specimens. CMV DNA may be detected in whole blood or leukocytes of individuals without active CMV disease. Some studies have shown a good association between high CMV DNA concentrations in plasma and active CMV disease[27,146] and suggest that detecting CMV DNA in plasma rather than in leukocytes may provide a better correlation with clinical disease, because the detection of CMV DNA in plasma suggests active viral replication.[146] However, it is clear that CMV DNA can also be detected in the plasma in patients without active CMV disease.[26,27] In addition to specimen type, assay format may be useful in distinguishing active disease from asymptomatic infection. For example, the pp67 mRNA detected in the NucliSens assay is expressed in high concentrations in patients with active disease and is not expressed during latent infection.[121] This has been supported in studies that have shown that the NucliSens assay is positive less frequently than assays that detect CMV DNA.[64] For CMV DNA-based assays, correlation with clinical disease requires quantifying CMV DNA to establish a concentration of CMV DNA that correlates with the likelihood of disease. The concentration of DNA that predicts disease will be higher in assays that use whole blood specimens than in those that test plasma specimens.

The clinical uses of CMV molecular assays are diverse and include assisting in decisions regarding initiating preemptive therapy, diagnosis of active CMV disease, and monitoring response to therapy. *Preemptive therapy* refers to the use of a laboratory test to identify a group of individuals at higher risk for developing CMV disease. For example, all members of the group would be tested for the presence of CMV DNA in their blood or plasma, and only those testing positive would be treated. Therapy is administered before development of symptoms in an attempt to prevent the development of active disease. By contrast, with *prophylactic therapy*, all patients in the group are treated, without further stratification of risk, thus involving treatment of a greater number of patients.

Molecular assays have utility for the diagnosis of active CMV disease, because CMV DNA concentrations are higher in patients with active CMV disease than in those with asymptomatic infection.[42,60,81,149,187] A study in liver transplant recipients using the Amplicor PCR assay showed that the median peak viral load in patients with asymptomatic infection was 1850 copies/mL compared with 55,000 copies/mL for those with active disease.[81] The viral load cutoff that was most predictive of the development of active disease was between 2000 and 5000 copies/mL of plasma. A similar study in renal transplant recipients using the Hybrid Capture assay showed that the risk of developing CMV disease increased from 1.5% with a viral load of 10,000 copies/mL of blood to 73% when the viral load was 1 million copies/mL of blood.[3] It is important to note that the viral load cutoffs differed in the two studies because of the use of different assays and differences in specimen type (plasma versus whole blood).

Once active CMV disease has been diagnosed, molecular assays are useful in monitoring response to therapy. Viral-load values decrease rapidly after beginning appropriate antiviral therapy, and several studies have reported that CMV DNA is cleared from the plasma within several weeks of initiating therapy.[26,27,82] Failure of viral loads to decrease promptly should raise concerns of possible treatment failure, because persistently elevated concentrations of CMV DNA (20,000 to 70,000 copies/mL in plasma) during therapy have been seen in patients with documented resistance of CMV to the therapy.[26] Molecular assays also have clinical utility in identifying patients at risk of relapsing CMV infection. In a group of solid-organ transplant recipients,[161] those patients with a detectable viral load after completing 14 days of ganciclovir therapy for CMV infection were at increased risk of relapse. Similarly an increased risk of relapse has been shown for patients with persistent pp67 mRNA after completing a course of therapy.[135] The rate of decline in CMV DNA after initiating therapy can be used to predict risk of relapse of CMV infection. In one study, CMV DNA was cleared from the plasma in 17 days for patients without recurrent CMV disease compared with 34 days for those with evidence of recurrent disease.[82] By following viral-load concentrations weekly after initiating antiviral therapy, it may be possible to identify those at risk of recurrent disease and thus intensify therapy and possibly prevent recurrent disease.

CMV DNA concentrations are also useful in assessing the risk of developing CMV disease in persons with AIDS. In a study by Spector et al,[166] detection of CMV DNA in plasma was associated with an increased risk of developing CMV disease and an increased risk of death. In addition, each $\log_{10}$ increase in viral load (i.e., each tenfold increase in concentration) was associated with a threefold increase in the risk of developing CMV disease. The clinical importance of CMV viral load in patients was further established in patients with advanced AIDS in whom the CMV DNA load was found to be more predictive of developing CMV disease or death than HIV-1 viral load.[165] A more recent study has identified individuals with a CD4+ cell count of less than 50 cells/mm^3 and an HIV-1 viral load of greater than 10,000 copies/mL of plasma as those at greatest risk of developing end-organ CMV disease.[57] In this group of individuals, a rise in CMV DNA above the limit of detection of either the Hybrid Capture or Amplicor PCR assays was associated with the development of CMV end-organ disease. This study identifies a group of HIV-1–infected individuals that may benefit from monitoring CMV viral load and preemptive therapy for the prevention of CMV end-organ disease.

A major challenge that remains for laboratories offering these assays is the difference in results among assays. A well-characterized CMV DNA standard reference material for use in calibrating the assays could greatly assist in achieving agreement of viral-load values among different tests, thus facilitating the determination of CMV concentrations that predict or correspond to clinical events.

MYCOBACTERIUM TUBERCULOSIS

Mycobacterium tuberculosis (MTb) causes a wide range of clinical infections, including pulmonary disease, miliary tuberculosis, meningitis, pleurisy/pericarditis/peritonitis, gastrointestinal disease, genitourinary disease, and lymphadenitis. MTb infection was in steady decline in the United States until the late 1980s into the early 1990s, when the number of reported cases began to increase. This resurgence in the number of infections was related to the AIDS epidemic, homelessness, and a decreased focus on tuberculosis control programs. By the late 1990s the infection rate had declined to an all time low.[34] One group in which the infection rate continues to rise is in foreign-born persons, which is due to immigration from countries with a high prevalence of MTb infections.[34] This increase in MTb infections focused considerable attention on the development of assays for the rapid diagnosis of MTb infections, and molecular methods were at the center of this effort. The goal was to design very sensitive assays that would allow for the direct detection of MTb from clinical specimens. However, this goal has proven to be more difficult to reach than originally anticipated.

The standard methods for detection of MTb include acid-fast bacilli (AFB) smear and conventional and liquid culture methods. The AFB smear is rapid, but has a poor sensitivity of 20% to 80%.[15] Another challenge with the AFB smear is that it cannot distinguish MTb from nontuberculous mycobacteria (NTM), such as *M. avium*-complex (MAC). This distinction is important because disseminated MAC and MTb are both common infections in persons with AIDS. Culture methods for the detection of MTb are sensitive, but growth detectable by standard methods may require 6 to 8 weeks in a culture. Growth often occurs more quickly in liquid culture than with conventional methods, but can still require weeks. With these limitations of culture methods, there was great enthusiasm for nucleic acid testing as a rapid, sensitive method for detection of MTb, especially given the needs to rapidly isolate patients with active, untreated disease and to initiate prompt therapy, particularly in immunocompromised hosts.

Two nucleic acid amplification tests have been approved by the FDA for detection of MTb from clinical specimens: the Amplified *Mycobacterium tuberculosis* Direct Test (MTD test; Gen Probe, Inc., San Diego), and the Amplicor *Mycobacterium tuberculosis* Test (Roche Diagnostics, Indianapolis). The MTD test is based on transcription-mediated amplification of ribosomal RNA. The Amplicor test is based on PCR technology and the target is the 16S ribosomal RNA gene. The MTD test has broader clinical applications, because it can be used to test both AFB smear–positive and smear-negative respiratory specimens. The Amplicor test is approved only for AFB smear–positive respiratory specimens. Neither assay has been approved for nonrespiratory specimens, which limits their clinical utility for diagnosis of extrapulmonary MTb infections. This is unfortunate,

because diagnosis of some of these infections is often difficult. In addition to these commercially available assays, LDTs are widely used, and a key advantage of these assays is the ability to test respiratory and nonrespiratory specimens.

Both the MTD test and the Amplicor test have a sensitivity of 95% to 98% when using AFB smear–positive respiratory specimens, and the specificity ranges from 99% to 100%. However, early studies showed that the sensitivity for AFB smear-negative specimens was ~50%.[32] Based on these data, it was clear that the test could not be used to rule out MTb infection on smear–negative respiratory specimens. This further limited the clinical utility of these tests, because it became clear that the nucleic acid testing would be used to supplement the AFB smear and culture rather than replace these testing modalities. Another limitation of the currently available nucleic acid assays is that they can be used only on specimens from patients who had not received antituberculosis therapy within the past 12 months. This limitation was included because DNA can persist in respiratory secretions (and other body fluids) for months after the mycobacteria are no longer viable.

The MTD test was subsequently reformulated and evaluated in a clinical trial comparing this test to a culture and to the probability of MTb infection as determined by a panel of experts.[87] The sensitivity and specificity of the test were 86% and 98%, respectively. The positive and negative predictive values were 91% and 97%, respectively. Based on this study, the reformulated MTD test was approved by the FDA for use on both AFB smear–positive and AFB smear–negative specimens. The CDC has established guidelines for the use of nucleic acid testing on respiratory specimens.[30,35] Patients with a positive AFB smear and a positive nucleic acid testing result should be presumed to have MTb infection, and there is no need for additional nucleic acid testing. If the sputum smear is AFB-positive, if two or three specimens are negative by nucleic acid testing, and if inhibition of amplification has been ruled out, then the patient can be presumed to have NTM infection. If the sputum specimen is AFB smear–negative and repeatedly positive by the MTD test (Note: the Amplicor test is not approved for use with smear-negative samples), then the patient can be presumed to have MTb infection. For patients with an AFB-negative smear, a negative nucleic acid test does not rule out MTb infection.

A key consideration with molecular assays is controlling for inhibition of amplification. This is particularly critical for the detection of MTb nucleic acid from respiratory specimens, because these specimen types often contain blood or glycoprotein, which can inhibit amplification. The Amplicor assay contains an internal control, and a negative result cannot be reported unless the internal control is detected. The MTD test does not contain an inhibition control, though many laboratories include such a control by adding a positive control material to a second aliquot of the clinical specimen.

An important role for molecular assays is in the diagnosis of extra-pulmonary MTb infections, such as meningitis, pleuritis, pericarditis, or peritonitis, because these infections can be very difficult to diagnose by traditional methods. The MTD and Amplicor tests have been used on CSF specimens for the diagnosis of MTb meningitis,[7,11,98] although the tests have not been approved by the FDA for this indication. In addition, PCR LDTs have been developed with the flexibility needed to test a variety of clinical specimens. As mentioned for respiratory specimens, it is critical to remember that a negative nucleic acid test result does not rule out extra-pulmonary MTb infection, and molecular assays using these complex body fluids should include an inhibition control.

Though there are considerable limitations to the currently available nucleic acid tests for the detection of MTb infection, they have a role in the clinical laboratory in that they can provide a rapid diagnosis. The goal would be to develop assays with a higher sensitivity (>99%) for AFB smear–negative specimens, because this may eliminate the need to culture specimens that are negative when tested in nucleic acid assays.

Hepatitis C Virus

HCV, an RNA virus, is a major cause of chronic liver disease. According to the National Health and Nutrition Examination Survey (NHANES) of 1988-1994, approximately 4 million Americans were infected with HCV and 2.7 million were estimated to have chronic infection. After acute infection, 80% to 85% of individuals develop a chronic infection, and 2% to 4% of these individuals develop cirrhosis and end-stage liver disease, making end-stage liver disease secondary to HCV the most common indication for liver transplantation in the United States.[129] The development of molecular testing for HCV infection has been a major advance in the clinical care of infected individuals, because the virus cannot be grown in a culture.

Detection and Quantification of HCV RNA

The applications of HCV RNA testing include assisting in the diagnosis of HCV infection, excluding HCV infection as the etiologic agent of symptoms, screening the blood supply, monitoring response to therapy, and determining the duration of therapy. Qualitative molecular assays are used to confirm the diagnosis of HCV infection, which is particularly important in distinguishing seropositive individuals who have cleared the infection from seropositive persons who have chronic infection. Individuals who have cleared the infection will not have detectable RNA, while those with persistent infection will have detectable RNA. Recent data from the CDC have shown that 95% of positive results of screening ELISA that have a signal-to-cutoff ratio (s/co) >3.8 can be confirmed as true positives.[29] For these specimens, confirmation testing is not routinely needed. For specimens with an s/co ratio of <3.8, confirmation testing should be done with either a recombinant immunoblot assay (RIBA) or by detection of HCV RNA. If HCV RNA detection is used as the confirmatory test, then RNA-negative specimens should

be tested in the RIBA. This is to distinguish a false-positive ELISA result from true infection. Alternatively, repeat testing for HCV RNA should be done, because viremia may be intermittent and HCV infection should not be ruled out based on one negative HCV RNA test. Qualitative molecular assays are also used to diagnose HCV infection in infants born to HCV-infected mothers. Since maternal IgG antibody can cross the placenta, these infants can be seropositive into the second year of life. Detection of HCV RNA in the plasma or serum of the newborn shortly after birth would be diagnostic of infection. Detection of HCV RNA in plasma or serum can be a useful diagnostic test in immunocompromised individuals, such as those with end-stage HIV-1 infection, because they may not mount a normal immune response to the virus and may not be seropositive.

Qualitative HCV RNA testing is also used to define a treatment response to interferon and ribavirin combination therapy for HCV infection because these assays are very sensitive, with lower limits of detection between 5 and 50 copies/mL plasma. Response to therapy is defined as an undetectable HCV RNA after completion of therapy, while a sustained response is defined as an undetectable viral load 24 weeks after completion of therapy.[116] More recently, qualitative HCV RNA assays have been developed for screening the blood supply. HCV RNA is detectable in serum during the "window period" between infection and seroconversion (when tests for HCV antibodies are negative). As most individuals with recently acquired HCV infection are asymptomatic, testing of blood donors for HCV RNA allows identification of individuals at risk for transmitting HCV infection who would have been missed if testing were done with only serological assays. Nucleic acid testing for HCV RNA has reduced the window period by an average of 26 days.[94] By screening the blood supply with HCV antibody testing alone, it was estimated that 1 in 100,000 units contained HCV RNA, but with the addition of testing by nucleic acid amplification technology (often called NAT) for HCV, the risk is projected to be reduced to 1 in 367,000 units.[94] Data from the first 2 years of experience with nucleic acid testing of the blood supply confirmed these estimates, because 1 in 259,000 screened units was found to be HCV RNA–positive and antibody-negative.[172,173]

HCV viral-load testing can be used to predict the response to antiviral therapy. Patients with viral loads above 2 million copies/mL of plasma are less likely to respond to interferon/ribavirin therapy than those with lower viral loads.[51,116,142] Although genotype is a stronger predictor of response to therapy than viral load (see below), recent studies have shown the utility of determining the viral load after 12 weeks of therapy. Patients who fail to have a $2\log_{10}$ drop in HCV RNA concentrations (i.e., concentrations are one one-hundredth the initial concentrations) at 12 weeks after initiating interferon and ribavirin have a 3% likelihood of responding to therapy compared with 65% for patients who do achieve a $2\log_{10}$ drop in viral load.[62,101] By determining HCV viral load at baseline and again after 12 weeks of therapy, patients who are very unlikely to respond to therapy can be identified earlier in the course of therapy. This will allow for discontinuation of potentially toxic drugs and a reduction in the cost of therapy. On the other hand, individuals with a $2\log_{10}$ drop in viral load will have therapy continued for either 24 or 48 weeks depending on the HCV genotype and other risk factors.

Several qualitative assays have been approved by the FDA for the detection of HCV RNA in plasma or serum specimens (Table 42-7). The Amplicor HCV test and the COBAS Amplicor HCV test (Roche Diagnostics, Indianapolis) are based on RT-PCR technology; the COBAS test allows for

TABLE 42-7 HCV RNA Tests In Clinical Use*

Test	Assay Method	Comments
Amplicor HCV Test v2.0 (Roche Diagnostics, Indianapolis)	RT-PCR	Qualitative, limit of detection 50 IU/mL
Versant HCV RNA Assay (Bayer Diagnostics, Tarrytown, NY)	TMA	Qualitative, limit of detection 5 IU/mL
In-Laboratory Developed	RT-PCR	Varies
Versant HCV RNA v3.0 Assay (Bayer Diagnostics, Tarrytown, NY)	bDNA	Quantitative, range 615-7.7 million IU/mL
Amplicor HCV Monitor Test v2.0 (Roche Diagnostics, Indianapolis)	RT-PCR	Quantitative, range 600-800,000 IU/mL
Laboratory Developed Test	RT-PCR	Quantitative, varies
Real-Time HCV Assays (ASR) (Roche Diagnostics and Abbott Diagnostics)	RT-PCR	Quantitative, range 10-50 IU/mL to 10-30 million IU/mL

For current FDA listings, see http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfRL/listing.cfm.

RT-PCR, Reverse transcription-polymerase chain reaction; *TMA*, transcription mediated amplification; *bDNA*, branched DNA; *ASR*, analyte-specific reagent.

*Excluding molecular testing for the blood supply.

automation of the amplification and detection steps. Both versions of the Amplicor test have a lower limit of detection of 50 international units (IU)/mL. The Versant HCV RNA Qualitative Assay (Bayer Diagnostics, Tarrytown, N.Y.) uses transcription-mediated amplification (TMA) and can detect as few as 5 IU of HCV RNA/mL of HCV RNA. In addition to these tests, RT-PCR LDTs are also used in some laboratories. Two additional qualitative assays are available only for screening the blood supply: the Procleix HIV-1/HCV assay (Gen-Probe, Inc., San Diego) based on TMA technology, which is FDA-approved,[84] and the AMPLISCREEN HCV Test v2.0 (Roche Diagnostics, Indianapolis), which is an RT-PCR assay. Both assays report a lower limit of detection of less than 50 IU/mL.

Various tests are available for the quantification of HCV RNA. The Versant HCV RNA 3.0 assay (Bayer Diagnostics Corp., Tarrytown, N.Y.) is the only currently FDA-approved assay for HCV viral-load testing (Table 42-7). The assay is based on bDNA technology, and has a broad dynamic range and a lower limit of quantification of 615 IU/mL. The Amplicor HCV MONITOR test (Roche Diagnostics, Indianapolis) has a similar limit of quantification (600 IU/mL), but a much more limited linear range. Dilution of the clinical specimen is needed to measure viral loads greater than 800,000 IU/mL. Several large clinical studies evaluating the efficacy of interferon/ribavirin therapy have used an RT-PCR assay developed by the National Genetics Institute (NGI) (SuperQuant). This assay has a dynamic range of 100 to 100 million copies/mL, although dilution of the specimen is required to cover the entire dynamic range. A recent advance in HCV testing has been the availability of several real-time RT-PCR assays.[93,109] These assays have a lower limit of detection similar to those seen for the qualitative HCV assays (10 to 50 IU/mL) and a broad dynamic that allows for the accurate quantification of HCV concentrations up to 10 to 50 million IU/mL.[93] The availability of these real-time assays could allow laboratories to replace both their current qualitative and quantitative tests. At this time, real-time tests are available as ASRs from Roche Diagnostics[93] and Abbott Laboratories (Abbott Park, Ill.).

Earlier versions of the Amplicor RT-PCR and bDNA assays did not accurately quantify all genotypes of HCV,[52,73] and usually underestimated the concentrations of genotypes 2 and 3. However, the current versions of the Amplicor RT-PCR (version 2.0), Versant bDNA (version 3.0), and real-time assays accurately quantify all HCV genotypes.[52,93,110] When reporting results as copies per milliliter, the viral-load values obtained with the Versant bDNA and Amplicor RT-PCR may disagree, due in part to the use of different calibrators. The availability of an established WHO international standard has allowed standardization of HCV assays with reporting of results as IU per milliliter.[157]

The intra-assay imprecision (SDs) of the HCV Versant bDNA and Amplicor RT-PCR assays ranges from 0.05 to 0.3 $\log_{10}$; the Versant bDNA assay is more precise.[73] The biological variation of HCV viral load ranges from 0.5 $\log_{10}$ to 0.75 $\log_{10}$.[70] Based on these data, changes in HCV viral load need to exceed 1 $\log_{10}$ (i.e., a tenfold change in concentration) to represent significant changes in viral replication.

HCV Genotyping

A hallmark of HCV infection is genetic heterogeneity, resulting from the low fidelity of the RNA-dependent RNA polymerase, which frequently introduces random nucleotide errors during viral replication. These replication errors could yield 10 to 100 nucleotide changes per position per year,[49] giving rise to many genetic variants (quasispecies) of the virus in a single patient. Based on the identification of these genomic differences, HCV has been classified into six major genotypes and multiple subtypes within each genotype.[22] There are geographic differences in the distribution of HCV types. In the United States approximately two-thirds of the infections are type 1, with the remaining being predominately types 2 and 3.[55,117]

The HCV genome contains well-defined 5′- and 3′-untranslated regions (5′UTR and 3′UTR). The 5′UTR is the most conserved portion of the genome and is frequently used as the target for molecular assays, including genotyping assays.[20] The HCV genome is divided into seven areas: the core region that encodes the capsid C protein, the E1 and E2 regions that encode the envelope proteins (gp33 and gp72), and several nonstructural protein regions (NS2, NS3, NS4, and NS5). The NS5B region shows less sequence homology than the 5′UTR, and sequencing of NS5B has been successfully used for genotyping HCV.[163]

As mentioned above, the probability of response to therapy depends on genotype. In one study, ~70% of patients with genotypes 2 and 3 had a sustained response after 12 months of combination therapy compared with only 30% of patients with genotype 1,[116] and no additional benefit was obtained by treating patients with genotype 2 or 3 beyond 24 weeks. In contrast, the response rate after 24 weeks of therapy for patients with genotype 1 was 16% compared with 28% after 48 weeks of therapy. These results have been confirmed in another randomized trial[142] comparing interferon 2b plus ribavirin with a placebo in patients with chronic HCV infection. Similar results were seen in a more recent study comparing peginterferon plus ribavirin with interferon plus ribavirin. A greater percentage of patients in the peginterferon plus ribavirin arm achieved a sustained virological response compared with those patients in the interferon plus ribavirin arm (56% versus 44%), respectively.[62] In addition, patients with HCV genotypes 2 or 3 had a significantly higher rate of sustained virological response than those with genotype 1. HCV genotyping, along with pretreatment viral load, age, gender, and the presence of hepatic fibrosis, can be used to determine the duration of antiviral therapy,[143] with genotype being the strongest predictor of a sustained virological response.

Several methods have been developed for genotyping and/or subtyping HCV, but most clinical laboratories use

either the reverse hybridization-based line probe assay (INNO-LiPA HCV II, manufactured in Belgium for Bayer Corp., Norwood, Mass.), or direct DNA sequencing. The INNO-LiPA assay is based on reverse hybridization of 5′UTR amplified products with genotype-specific probes.[174] This assay is convenient to use for many clinical laboratories because genotyping can be done directly from the amplicons generated in the Amplicor HCV Test (Roche Diagnostics, Indianapolis). The biotin-labeled amplified products are reverse-hybridized to the specific probes on the INNO-LiPA strips; streptavidin conjugated with alkaline phosphatase is added, followed by substrate addition. A purple/brown line develops where there is sequence homology between the biotinylated PCR products and the probe, and the genotype is determined based on the pattern of probe hybridization. The INNO-LiPA HCV II discriminates and identifies HCV genotypes 1a, 1b, 2a/c, 2b, 3a, 3b, 3c, 4, 5a, and 6a.[175] The INNO-LiPA is accurate in typing HCV, but cannot reliably subtype HCV.[4,195] There is not sufficient sequence variation in the 5′UTR to allow distinction between subtypes 2a and 2c, and reverse hybridization data of subtypes 1a and 1b may be discordant with NS5B in ~10% of cases.[175] Currently this is not a significant limitation of the assay because treatment decisions are based on viral genotype not subtype. In addition, the INNO-LiPA method is user-friendly and well suited for routine use in clinical laboratories that perform HCV genotyping.

Automated sequencing assays, both developed commercially and in-laboratory, are available to genotype HCV, and the genomic regions commonly used include 5′UTR,[20] NS5B (163), and core.[21] Sequencing methods require sequence alignment and comparison with reference sequences to determine the genotype and subtype. An HCV genotyping kit based on automated sequencing (Trugene HCV 5′NC, Bayer Diagnostics) targets the 5′NC region. Though this assay can accurately type HCV, like the INNO-LiPA assay it is unable to accurately subtype the virus.[132] When more variable regions of the virus are sequenced, such as NS5B, it is possible to determine both viral type and subtype.[163]

There have been several studies comparing the performance of the INNO-LiPA HCV II assay and automated DNA sequencing methods. One study found a 91% concordance rate between the two assays.[5] A more recent study compared the performance characteristics of the Trugene HCV assay and the INNO-LiPA.[132] Both methods were able to genotype 105 of the 106 serum specimens. There was concordance at the genotype level for 103 of 104 (99%) specimens. Sequence analysis of the NS5B region supported the INNO-LiPA result for the single genotype discrepant result. No subtype was called for 36 (34%) specimens typed by INNO-LiPA and 20 (19%) of those typed by Trugene HCV assay. Mixtures of genotypes were successfully identified with both methods, with the INNO-LiPA assay detecting populations making up at least 5% of the total population, and the Trugene HCV assays detecting populations of at least 10%. The overall performance of the two assays was similar and both assays can accurately type HCV, but neither method should be used for subtyping.[132]

A 2002 study reported on the use of real-time PCR with melting curve analysis as a method to genotype HCV.[23] Using a single pair of fluorescence resonance energy transfer (FRET) probes, it was possible to distinguish types 1a/b, 2a/c, 2b, 3a, and 4 on the basis of differences in melting temperatures. This method showed good concordance with INNO-LiPA. Of the 124 samples tested with both methods, 13 were nontypable by either of the methods; however, there was agreement for 108 of the remaining 111 samples. All three discrepant samples typed as 2a/c by melting curve analysis, while 2 of the 3 were typed as 2b by INNO-LiPA. The remaining sample typed as 1 by INNO-LiPA, which was confirmed by sequence analysis. Real-time PCR with melting curve analysis is a reliable method for typing HCV. As with other methods using the 5′UTR of the virus, it will not accurately subtype all samples.

CHAPTER 43

Pharmacogenetics

Gwendolyn A. McMillin, Ph.D., D.A.B.C.C.,
Mark W. Linder, Ph.D.,
and Bonny Lewis Bukaveckas, Ph.D.

The primary objective of pharmacogenetic testing is to predict how people will respond to medicines and other potentially toxic or bioactive xenobiotics based upon certain genetic characteristics. Pharmacogenetics may also help explain why an adverse drug reaction (ADR) occurred. The term pharmacogenetics has been pieced together from the words pharmacology (the study of drugs, drug action, and metabolism) and genetics (the study of how traits are inherited). Pharmacogenetic testing in a clinical setting links patient genetics (genotype) to predicted differences in the pharmacokinetics or pharmacodynamics of medications or other exogenous compounds.

Clinical pharmacogenetic test results are primarily useful for guiding medication selection and dosing. Specific dosing guidelines based on pharmacogenetic information are being developed to support the application of these test results for therapeutic drug management.[69,80,93] Such individualized pharmacotherapy is anticipated to reduce the number of ADRs, a leading cause of morbidity and mortality in the United States (see Table 43-1). For a more in-depth discussion of pharmacogenetics, the reader is referred to several excellent reviews.*

The goal of this chapter is to familiarize the clinical chemist with pharmacogenetic testing. This chapter begins with a discussion of general issues, including potential tests to offer in the clinical laboratory, choosing appropriate testing strategies, characteristics of a gene that make it a good candidate for pharmacogenetic testing, and characteristics of medications or other xenobiotics that support the need for pharmacogenetic testing. In the following sections, we provide detailed information for six well-characterized and polymorphic genes (*TPMT, CYP2D6, CYP2C19, CYP2C9, NAT1,* and *NAT2*). Variation in these genes contributes to intersubject variation in enzyme activity, kinetics, substrate specificity, and/or stability. Such variation is reflected in the ability of an individual to appropriately respond to medications that are substrates of these enzymes. This alteration in response to the medication defines the phenotype. The correlation of phenotypes and genotypes for these and several other proposed genetic targets is discussed in this chapter as well.

DEFINING PHARMACOGENETIC TARGETS AND WHAT TESTING TO CONSIDER

The response to drugs and other xenobiotics (foreign compounds absorbed by the human body) depends on many processes, such as route of administration, amount absorbed, any biotransformation (metabolism) that occurs, affinity of the parent compound and metabolite(s) for endogenous receptor(s), and the process of elimination.[40] For simplicity sake, we will use the term "drug(s)" throughout this chapter with the understanding that many principles of pharmacogenetics that apply to medications may also apply to other xenobiotics. Each process mentioned above involves several proteins that are coded from corresponding genes. Consequently, pharmacogenetic targets include any polymorphic gene that encodes for the many different proteins involved in these processes. To date, the best-studied pharmacogenetic targets are those involved in drug metabolism. Common features of pharmacogenetic tests of proven usefulness include: (1) the enzyme of interest is the primary pathway for metabolism of the drug, (2) changes in enzyme activity resulting from genetic polymorphism have a significant effect on the relationship between dose and plasma concentration, (3) the efficacy and/or toxicity of the drug correlate with changes in plasma drug concentration, and (4) the drugs affected by the pharmacogenetic variability possess a narrow therapeutic index. Further, pharmacogenetic

TABLE 43-1 Estimated Occurrence of Adverse Drug Events in the USA in 1994, in Thousands (95% confidence interval)

	ADRs in Patients While in Hospital	ADRs Responsible for Patient Admission to a Hospital	Total ADRs
All severities	3670 (2618-4596)	1547 (1033-2060)	4987 (3976-5995)
Serious	702 (635-770)	1547 (1033-2060)	2216 (1721-2711)
Fatal	63 (41-85)	43 (15-71)	106 (76-137)

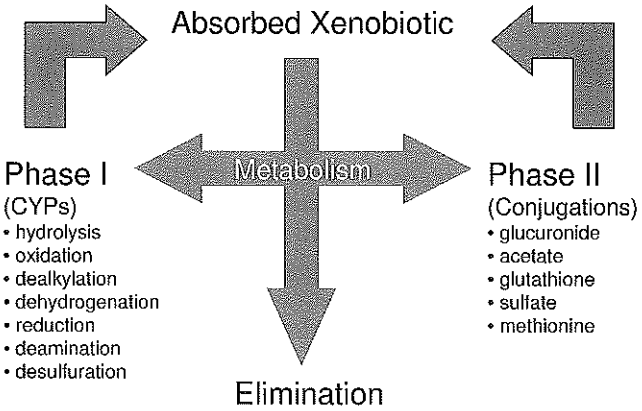

Figure 43-1 Simplified scheme of the primary metabolic reactions associated with xenobiotic handling in humans. Absorbed xenobiotics (drugs or other exogenous compounds) may be eliminated without biotransformation or be transformed into a metabolite through Phase I and/or Phase II reactions. The metabolite may be further metabolized by Phase I or Phase II reactions before elimination. Phase I reactions are primarily oxidative and are most commonly mediated by cytochrome P450 (CYP) isozymes. Phase II reactions involve conjugations to form glucuronides, acetates, and other adducts.

testing is of particular usefulness for those drugs that require a long period of time to establish efficacy or to optimize dose. Advocates of pharmacogenetics anticipate that future testing opportunities will include the ability to identify a population of nonresponders for a particular drug. Examples of drug classes likely to benefit from pharmacogenetic testing include cancer chemotherapeutics, immunosuppressants, antidepressants, antipsychotics, anticoagulants, antihypertensives, cardiac medications, and lipid-lowering therapies.

In general, drug metabolism serves to inactivate a substrate and increase water solubility of the substrate for excretion, bioactivate a substrate or prodrug (e.g., codeine and cyclophosphamide) to an active or mutagenic principle, or less commonly, extend the elimination half-life of a pharmacologically active or potentially toxic metabolite.[40,102] Metabolic reactions are often divided into Phase I and Phase II categories, as depicted in Figure 43-1.

Phase I reactions convert the parent compound into a more polar metabolite by introducing or removing a single functional group. Examples include oxidation, reduction, and hydrolysis. Most Phase I reactions are oxidative and are mediated by cytochrome P450 isozymes (CYPs). CYPs are heme-containing enzymes that are synthesized from a superfamily of *CYP* genes and are classified into families, and further into subfamilies, based on amino acid homology. The primary *CYP*s that are believed to contribute to drug metabolism are *CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1,* and the *CYP3A* family. All of these *CYP* families exhibit genetic variation that has been associated with clinically significant phenotypical differences caused by changes in enzyme activity, stability, and/or substrate affinity. In addition to the genetic variability, many CYP isoenzymes are susceptible to dramatic differences in expression (>1000-fold), caused in part by induction or inhibition mediated by substrates. Products of Phase I reactions may be eliminated or undergo additional modification, such as through Phase II reactions. Phase II reactions may occur independent of, or before, Phase I reactions.

Phase II enzymes are generally transferases involving enzyme-mediated conjugation with acetyl, glucuronyl, amino acid, or sulfate groups. These enzymes are not typically induced or inhibited to the same degree as CYPs. However, exhausting the substrates or cofactors for transfer, such as glutathione or acetyl-CoA, will prevent the corresponding transferase reactions from occurring.[40,102,110]

APPROACHES TO PHARMACOGENETIC TESTING

Pharmacogenetics is important to patient care because for many drugs there are interindividual differences in drug metabolism and drug response. These differences significantly alter the safety and success of therapy. Pharmacogenetic testing allows the physician to predict that a patient is likely to fail therapy or suffer an ADR before initiating therapy. This knowledge can lead to a change in drug dosage or drug selection, thus avoiding an undesired outcome.

Two major approaches are available to predict how well an individual will metabolize a medication: phenotyping

TABLE 43-2 Comparing Phenotype and Genotype Testing Strategies

	Phenotype	Genotype
Represents	"State," represents current response; may not represent inheritance	"Trait," represents inheritance; may not be consistent with the phenotype
Sensitive to gene expression	Yes	No
Sensitive to protein function	Yes	No
Requires collection of multiple specimens	Commonly	No
Requires administration of a probe drug	Commonly	No
Other limitations	Specimen instability for enzyme or other protein of interest may lead to inaccurate results May not be appropriate for a patient who recently received a blood transfusion	May not include all clinically relevant genes and/or alleles Genotype to phenotype relationship (interpretation) may not be known

and genotyping. Phenotyping is accomplished by testing metabolic activity—either by administering the patient a safe drug, often called a probe drug, that is known to be metabolized by the same enzyme or pathway as the intended therapeutic drug, or alternatively, by measuring the drug metabolizing enzyme activity using peripheral blood cells as a surrogate to the metabolism of the whole patient.[89] Examples of probe drugs include dextromethorphan for assessing CYP2D6 activity and caffeine for NAT2. Examples of enzyme-based phenotyping tests that have been successfully implemented include pseudocholinesterase, for detecting individuals with susceptibility to prolonged apnea when given succinylcholine or other similar medications; thiopurine S-methyltransferase (TPMT), for detecting individuals with susceptibility to hematological toxicity with azathioprine (AZA) or 6-mercaptopurine (6-MP); and glucose-6-phosphate dehydrogenase (G6PD), for detecting susceptibility to hemolysis in response to drugs such as primaquine, sulfonamides, chloramphenicol, and vitamin K. These techniques directly measure drug metabolism phenotype and, under highly controlled circumstances, provide the most meaningful information. There are, however, several limitations to the phenotypical approach. For example, the probe compound must be easy to administer in the target population, be relatively inexpensive, and exhibit pharmacokinetics that support convenient collection of specimens from the patient. Even with these variables controlled, phenotyping may be difficult to accomplish because of other potentially confounding factors, such as diet, comedications, recent blood transfusion, consumption of alcohol or over-the-counter medications, and disease status. The length of time required to perform the associated enotyping assays may also complicate and compromise value of direct phenotyping. Many enzymes are essed in higher quantities in neonates. In a study of 60 full-term newborns, TPMT activity was >50% higher than in race-matched healthy adults, but displayed the same trimodal distribution observed in adults.[90] Thus phenotyping illustrates the "state" rather than the "trait."

Pharmacogenetics, that is genotyping, is the second major approach to predicting drug metabolism and drug response. Pharmacogenetics may be useful for predicting pharmacodynamic response by identifying inherited genetic characteristics that either account for differences in phenotype from a structural basis or are clearly associated with phenotype through rigorous clinical studies. Neither phenotyping nor pharmacogenetic testing is intended to replace the need for clinical assessments of drug response, or replace the need for therapeutic drug monitoring (TDM). Several considerations of these two testing approaches are summarized in Table 43-2. Examples of both approaches will be given throughout this chapter; however, more emphasis is given to the pharmacogenetic approaches because of the recognition of the growing evidence supporting genotyping as a superior means of classifying enzymatic capacity. That evidence includes the facts that genotyping assays are less expensive, are more reproducible between laboratories, are not subject to the intraindividual variability because of a specific set of clinical conditions or expected biological variations (i.e., hormonal fluctuations[65]) that complicate phenotyping assays, and are less invasive (i.e., a single blood sample for genotyping; several samples for phenotyping). It is estimated, for example, that genotyping of *CYP2D6* can reliably predict the phenotype 80% to 90% of the time.

Although genotyping has many advantages over phenotyping, there are limitations to genotyping that must be recognized. For example, some of the assays using target amplification are prone to false negatives because they rely on the presence or absence of a polymerase chain reaction (PCR) product. Short of sequencing the entire gene, cur-

rently available genotyping techniques cannot detect all possible variants. Because of the large amount of variation in many genes, suites of variants are screened, potentially missing some important genetic variations because the patient possesses a rare or novel polymorphism that is not detected by the screen.[108] Further, polymorphisms with unknown clinical significance may also be identified by some techniques. Extreme care must be taken to ensure that these data are not misinterpreted.

Another disadvantage of genotyping is that it may not accurately predict function of the expressed protein. Continuing to use *CYP2D6* as an example, it has been shown that patients of a single common genotype have dextromethorphan to debrisoquine ratios (metabolic phenotypes) that span a 1000- to 10,000-fold range. The precise reason for this broad range is unknown but it is probably related to individual differences in expression of the *CYP2D6* gene, inherent alternative metabolic pathways, significant interlaboratory and intraindividual variability in phenotype measurements, and possible combinations of other minor undetected genetic polymorphisms in the *CYP2D6* gene.[130]

Finally, specific interactions between the target enzyme or protein and other drugs, chemicals, or some foods can change the phenotype, such as by converting a "normal" or extensive metabolizer phenotype to a poor metabolizer phenotype. For example, grapefruit juice has been shown to inhibit CYP3A4,[57,78,105] and many antidepressant medications (e.g., tricyclic and selective serotonin reuptake inhibitors) are known to act as both substrates and inhibitors of CYP2D6.[7,110] Such drug and food interactions can have extremely important consequences for patients and can be difficult to both recognize and monitor.

CLINICAL APPLICATION OF PHARMACOGENETIC TESTING

Pharmacogenetic testing is only clinically useful when there is sufficient information to interpret the results. This information must be derived from in vivo, human studies demonstrating a clear phenotype. Many examples of this type of information can be found in the peer-reviewed literature, but most data are based on retrospective studies, and there is no single printed source in which all of this information has been collated. The Pharmacogenetics and Pharmacogenomics Knowledge Base[6] is a publicly available internet research tool developed by Stanford University with funding from the National Institutes of Health (NIH) and is part of the NIH Pharmacogenetics Research Network (PGRN), a nationwide collaborative research consortium. Its aim is to aid researchers in understanding how genetic variation among individuals contributes to differences in reactions to drugs. This regularly updated database provides genetic and clinical information derived from research studies at various medical centers in the PGRN.

Currently published dosing guidelines relate to specific combinations of pharmacogenetic markers and drugs. For example, Kirchheiner et al have published dose recommendations for 20 antidepressant medications based on single versus chronic maintenance therapy and genotypes for both *CYP2D6* and *CYP2C19*.[70] Average recommended adjustments of "standard" doses vary from 20% of the usual dose for poor metabolizers using venlafaxine, paroxetine, or desipramine to 300% of the usual dose for ultrarapid metabolizers using mianserin. Similar work suggesting specific dose ranges or adjustments based on phenotype-genotype relationships has been conducted with other substrates of these CYP isoenzymes (see CYP2D6 and CYP2C19 sections later in this chapter), AZA and 6-MP (see TPMT section of this chapter), warfarin (see CYP2C9 section of this chapter), and antipsychotics.[71]

Many ongoing clinical trials for efficacy and toxicity of new pharmaceutical products or new indications for previously developed pharmaceuticals have employed pharmacogenetic testing. Thus it is anticipated that pharmacogenetic guidelines and possibly tests will be simultaneously released to market with the pharmaceutical. In addition, medications that were previously removed from development because of adverse reactions may be reconsidered if a genetic test can be demonstrated to identify individuals at high risk for ADRs.

BEST EXAMPLES OF CLINICALLY RELEVANT PHARMACOGENETIC TARGETS

For each of six genes, *TPMT, CYP2D6, CYP2C19, CYP2C9, NAT1,* and *NAT2,* this chapter provides an overview of background information, the relationship between genotype and phenotype, unique testing methods, and clinical applications of testing.

THIOPURINE S-METHYLTRANSFERASE

TPMT is a Phase II metabolic enzyme that catalyzes the inactivation of 6-MP by S-methylation, thus preventing it from forming thioguanine nucleotides (TGN).[5,116] TPMT also affects AZA, which is a prodrug metabolized to 6-MP, as shown in Figure 43-2. Endogenous substrates for TPMT are currently unknown. AZA and 6-MP are used in the therapeutic management of a diverse range of conditions, including leukemia, rheumatic diseases, inflammatory bowel disease, and solid organ transplantation. These agents are cytotoxic, acting via incorporation of TGN into DNA. Outside of the bone marrow, these agents can be oxidatively inactivated by xanthine oxidase or methylated by TPMT. In hematopoietic tissue, however, the effect of xanthine oxidase is negligible, leaving TPMT as the only significant inactivation pathway. Thus hematopoietic tissues are susceptible to damage in cases in which TPMT activity is very low. TPMT activity is highly variable in all large populations studied to date; approximately 90% of individuals have high activity 10% have immediate activity, and 0.3% have low or und tectable enzyme activity. This tri-modal activity is a dir result of enhanced proteasomal degradation of TPM

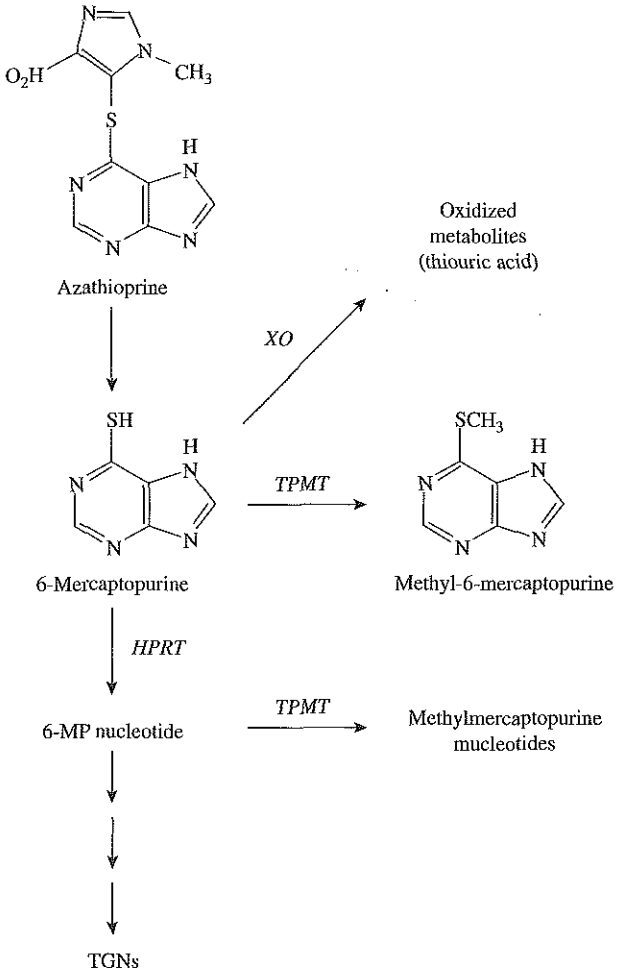

Figure 43-2 Simplified scheme of the metabolism of azathioprine and 6-mercaptopurine to 6-thioguanine nucleotides (TGNs). *TPMT,* Thiopurine S-methyltransferase; *XO,* xanthine oxidase; *HPRT,* hypoxanthine phosphoribosyltransferase. *(Redrawn from Clunie GP, Lennard L. Relevance of thiopurine methyltransferase status in rheumatology patients receiving azathioprine. Rheumatology (Oxford) 2004;43:13-8.[23] Reproduced by permission from Oxford University Press.)*

Numerous studies have shown that TPMT-deficient patients are at high risk for severe, and sometimes fatal, hematological toxicity.

Genotype to Phenotype

The molecular basis for variable TPMT activity has now been defined for the majority of patients.[92] TPMT activity is inherited as an autosomal co-dominant trait,[133] exhibiting genetic polymorphism in all populations studied to date. Eleven *TPMT* alleles have been identified, including nine single nucleotide polymorphisms (SNPs) leading to amino acid substitutions, *TPMT*2, *3A, *3B, *3C, *3D, *5, *6, *7, *8;* one change leading to the formation of a stop codon, *TPMT*3D;* and a change that destroys a splice site: *TPMT*4.* Three alleles, *TPMT*2, *3A,* and **3C,* account for about 95% of intermediate or low enzyme activity cases (Figure 43-3). Three alleles associated with lower enzyme activity have

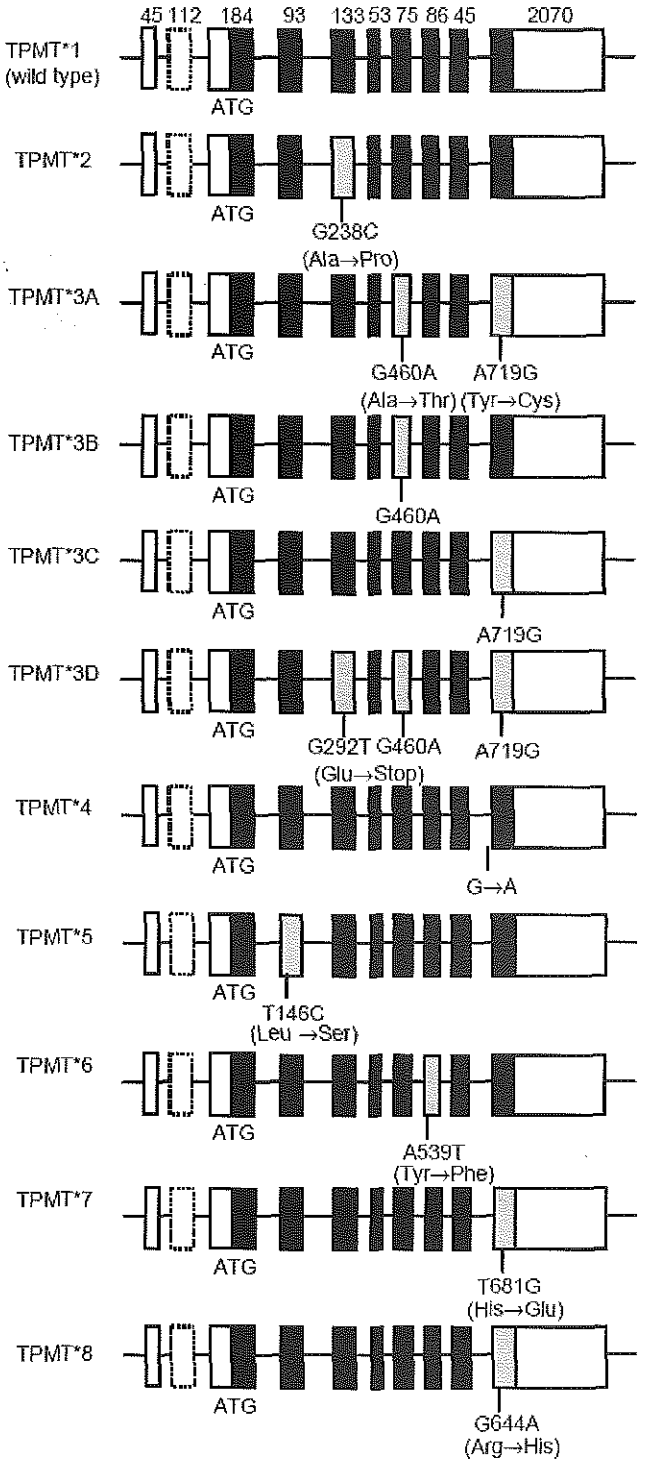

Figure 43-3 Thiopurine S-methyltransferase *(TPMT)* allele variants. Gray boxes represent mutations that result in amino acid changes. TPMT*4 is a 5′ splice site mutation for exon 10 that does not alter an amino acid. White boxes represent untranslated regions. Black boxes represent exons in the open reading frame. The dashed box represents exon 2, which was detected in 6.25% of human liver cDNAs during initial evaluation. *(From McLeod HL, Siva C. The thiopurine S-methyltransferase gene locus—implications for clinical pharmacogenomics. Pharmacogenomics 2002;3:89-98. Reproduced by permission from Future Medicine Ltd [London].)*

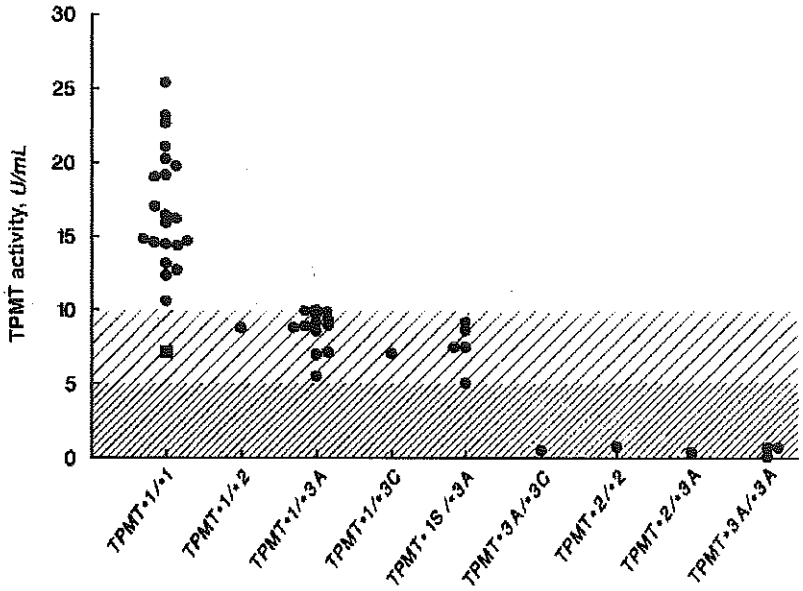

Figure 43-4 Thiopurine S-methyltransferase (TPMT) activity as related to genotypes determined by mutation-specific polymerase chain reaction methods. The heavily shaded area depicts the range of TPMT activity in erythrocytes that defines TPMT deficiency (<5 U/mL of packed red blood cells), the lightly shaded area depicts intermediate activity that defines TPMT heterozygous phenotypes (5 to 10 U/mL of packed red blood cells), and the nonshaded area depicts the range of TPMT activity in patients who have homozygous wild-type phenotypes. Black circles indicate patients with concordant genotype and phenotype; the black square indicates one patient with discordant genotype and phenotype *(TPMT*1/*1)*. *(From Yates CR, Krynetski EY, Loennechen T, Fessing MY, Tai HL, Pui CH, et al. Molecular diagnosis of thiopurine S-methyltransferase deficiency: genetic basis for azathioprine and mercaptopurine intolerance. Ann Intern Med 1997;126:608-14. Reproduced by permission from the American College of Physicians.)*

enhanced rates of proteolysis of the alloenzymes (protein products of the variant alleles). The presence of a *TPMT* variant allele is 90% sensitive and 99% specific for predicting TPMT phenotype; patients with one wild-type allele and one of these variant alleles (i.e., heterozygous) have intermediate activity and patients inheriting two variant alleles are TPMT deficient (see Figure 43-4).[112]

Testing

TPMT testing may occur via at least three routes: biochemical phenotyping by determining TPMT activity within erythrocytes from the patient; metabolic phenotyping by determining concentrations of 6-MP and thioguanine; or genotyping. Biochemical phenotyping depends on stable enzyme activity between the times of blood collection and analytical testing. This approach is therefore challenged by storage and stability concerns and is limited to patients who have not received a blood transfusion over the weeks previous to TPMT testing. Metabolic phenotyping requires that AZA or 6-MP be administered before testing. This approach is therefore most useful for patients who have experienced an adverse event or for monitoring therapy in those for which TPMT activity is known to be impaired. *TPMT* genotype correlates well with TPMT activity in leukemia cells, as would be expected for germline mutations. By using PCR-based assays to detect the three signature mutations in these alleles, a rapid and relatively inexpensive assay may identify >90% of all variant alleles. In Caucasian populations, *TPMT*3A* is the most common variant *TPMT* allele (3.2% to 5.7% of *TPMT* alleles), although *TPMT*3C* has an allele frequency of 0.2% to 0.8% and *TPMT*2* represents 0.2% to 0.5% of *TPMT* alleles.[2,24,104] Studies in Caucasian, African, and Asian populations have revealed that the frequency of these variant *TPMT* alleles differs among various ethnic populations. East and West African populations have a frequency of variant alleles similar to Caucasians, but the variant alleles in the African populations were predominantly *TPMT*3C*.[2] Among African-Americans, *TPMT*3C* is the most prevalent allele, but *TPMT*2* and *TPMT*3A* are also found, reflecting the integration of Caucasian and African-American genes in the U.S. population.[58] In Japanese and Chinese populations, *TPMT*3C* is almost exclusively the causative variant allele.[24,73,74,84] In other Asian populations, the *TPMT*3C* is also predominant, but the *3A and *6 alleles have also been observed in Indian and Malay children, respectively.[84]

Genotyping tests, however, may not detect TPMT deficiency in all patients, particularly those with a rare unknown but clinically significant variant. Compound h erozygotes also present a challenge to PCR-based ge

testing in this gene. For example patients with the heterozygous genotype *TPMT*1/*3A* have a 35% risk of hematopoietic toxicity versus a 7% risk for patients with homozygous wild-type genotype. Alternatively, patients with the *TPMT*3B/*3C* genotype are TPMT-deficient and are at very high risk for thiopurine toxicity. These genotypes are impossible to distinguish when using conventional PCR genotyping.[18] The *TPMT*3B* allele is very rare (<1% of variant alleles); however, its presence can have grave clinical consequences. A haplotyping method has been published that discriminates *TPMT*1/*3A* from *TPMT*3B/*3C* using genomic DNA.[88]

Clinical Application

TPMT was the first widely used pharmacogenetic marker for individualizing drug therapy based on a patient's biochemical phenotype (erythrocyte enzyme activity) or genotype. Patients with a "low methylator" status (homozygous variant or compound heterozygote) may tolerate standard doses, but are at significantly greater risk of toxicity, often necessitating a lower dose of these medications (as low as 5% of standard doses). Prospective determination of functional TPMT status is useful for preventing mercaptopurine toxicity.[23,116] Whether TPMT testing is based on phenotype or genotype, the goal is individualized dosing, and controlled systemic exposure.[33]

An analysis of mercaptopurine therapy for childhood acute lymphocytic leukemia (ALL) found that TPMT-deficient patients tolerated full doses of mercaptopurines for only a brief period (7% of the scheduled weeks of therapy), whereas heterozygous and homozygous wild-type patients tolerated full doses for 65% and 84% of scheduled weeks of therapy during the 2½ years of treatment, respectively. The percentage of weeks in which mercaptopurine dosage had to be decreased to prevent toxicity was 2%, 16%, and 76% in wild-type, heterozygous, and homozygous variant individuals. Collectively, these studies demonstrate that the influence of *TPMT* genotype on hematopoietic toxicity is most dramatic for homozygous variant patients, but is also of clinical relevance for heterozygous individuals, which represent about 10% of patients treated with these medications.

A potentially valuable role for TPMT status testing is before intravenous AZA loading, a strategy shown to be safe in the management of Crohn's disease. Dose-related toxicities resulted in AZA discontinuation in 10% to 20% of cases, and it was estimated that over 6 months, 20% of patients would need TPMT analysis to avoid one serious adverse event. TPMT status testing before taking AZA has been modeled to be cost-effective in a variety of theoretical situations. Analysis of some recent studies suggests that by optimizing the maximum AZA dose between 0.75 and 3 mg/kg/day depending on TPMT status testing (with a drastic reduction in dosage for patients homozygous for variant *TPMT* alleles), considerable cost savings can be made by avoiding hospitalization and rescue therapy for leukopenic events.[86,126,129] Furthermore, one study reported that the median dose reduction required for TPMT-deficient patients was 90.8% (range, 50% to 94%) and median dose reduction in *TPMT* heterozygotes of 67% (range, 0% to 93%).[34] This study included only patients referred for hematopoietic toxicity. However, previous studies have reported that heterozygous patients needed only 15% to 30% dose reduction to avoid serious side effects.[109]

Although detection of *TPMT* polymorphisms is thought to prospectively identify approximately 10% of patients likely to experience dose-limiting toxicity from AZA and 6-MP therapy, toxicity is estimated to occur in 15%-28% of patients. Thus, toxicity related to thiopurine therapeutics cannot be explained by known *TPMT* polymorphisms alone. Cao and Hegele have described an inosine triphosphate (ITPA)–deficient phenotype that may provide an additional mechanism for thiopurine-related toxicity.[20] This phenotype, like TPMT deficiency, is clinically benign until a patient is exposed to a thiopurine therapeutic such as 6-MP or AZA. The ITPA deficiency phenotype is associated with a 94C>A polymorphism of *ITPA*, and approximately 25% residual red cell ITPase activity. Consequently, the metabolite 6-thio-ITP accumulates and may contribute to toxicities previously associated only with TPMT deficiency. Although currently not well characterized, determination of genotypes for *TPMT, ITPA*, and potentially other genes may form the best strategy for predicting risk of adverse reactions associated with AZA and 6-MP therapy.

Cytochrome P450 2D6 (CYP2D6)

Cytochrome P450 2D6 (CYP2D6), originally named debrisoquine hydroxylase, is a Phase I enzyme known to metabolize more than 100 drugs and environmental toxins as substrates.[42,110] Examples of drugs and drug classes metabolized by CYP2D6 are shown in Table 43-3. CYP2D6 is also inhibited by several compounds, some of which are substrates. More than 80 genetic variants have been described in the *CYP2D6* gene.[5] In general the variants can be grouped according to the resulting alterations in protein function. These groupings correlate well with the four major phenotypes described historically for CYP2D6: extensive (normal) metabolizers (EM), poor metabolizers (PM), intermediate metabolizers (IM), and ultrafast or rapid metabolizers (UM). The major coding sequence variants described result in decreased function with the exception of gene duplication, which results in increased metabolic capacity if a functional gene has been duplicated.[141] Of Caucasians, approximately 5% are UM, and 5% to 10% are PM. Only 1% to 3% of African-Americans and Asians are PM, but many are IM.

Genotype to Phenotype

The relationship between the CYP2D6 enzyme metabolic rate (phenotype) and the *CYP2D6* genotype has been extensively characterized.[1,76,98,103,111] Genetic variability accounts for the tetra-modal distribution of CYP2D6 activity described historically by the phenotypes. The rank order of

From Flockhart DA. Clinically relevant drug interaction table. This table is updated frequently. http://medicine.iupui.edu/flockhart/table.htm (Accessed August 30, 2004).[36] Reproduced with the permission of David A. Flockhart, M.D., Ph.D.

metabolic capacity is ultrarapid metabolizers (UM) > extensive metabolizers (EM) > intermediate metabolizers (IM) > poor metabolizers (PM), representing approximately 5% to 7%, 60%, 25%, and 10% of most populations, respectively. A summary of *CYP2D6* alleles and consequences is shown in Figure 43-5.

CYP2D6 phenotypes have historically been determined through the use of probe drugs. Urine collected at a specified time after administration of the probe drug (e.g., 8 hours) is analyzed for the parent drug and a metabolite that is primarily generated via CYP2D6. The ratio of parent and metabolite concentrations is referred to as the metabolic ratio (MR). Example parent-metabolite pairs used commonly as probe drugs for CYP2D6 include dextromethorphan/dextrorphan, debrisoquine/4-hydroxydebrisoquine, and nortriptyline/10-hydroxynortriptyline. The need to administer a probe drug and to collect urine over several hours has always limited the practical utility of patient phenotyping. Although the MR is theoretically a good indicator of enzyme expression and function at the time of the test, marked variation has been demonstrated in this phenotypical characteristic for nearly every *CYP2D6* genotype (see Figure 43-6).[22] Interpretation of MRs must consider the specificity of the probe drug for the CYP2D6 and also the elimination kinetics of the parent and metabolite.

Testing

The *CYP2D6* gene is relatively challenging to genotype because of the presence of pseudogenes and also because of the need for identification of gene dose, specifically duplications and deletions of the gene. *CYP2D6* pharmacogenetic screening protocols may detect only the most common variants. For example, testing for 7 variants in the gene is estimated to predict the CYP2D6 phenotype with >95% reliability.[81]

To separate *CYP2D6* from structurally similar pseudogenes, *CYP2D6* genotyping protocols often employ long-PCR or nested PCR strategies with a first PCR step

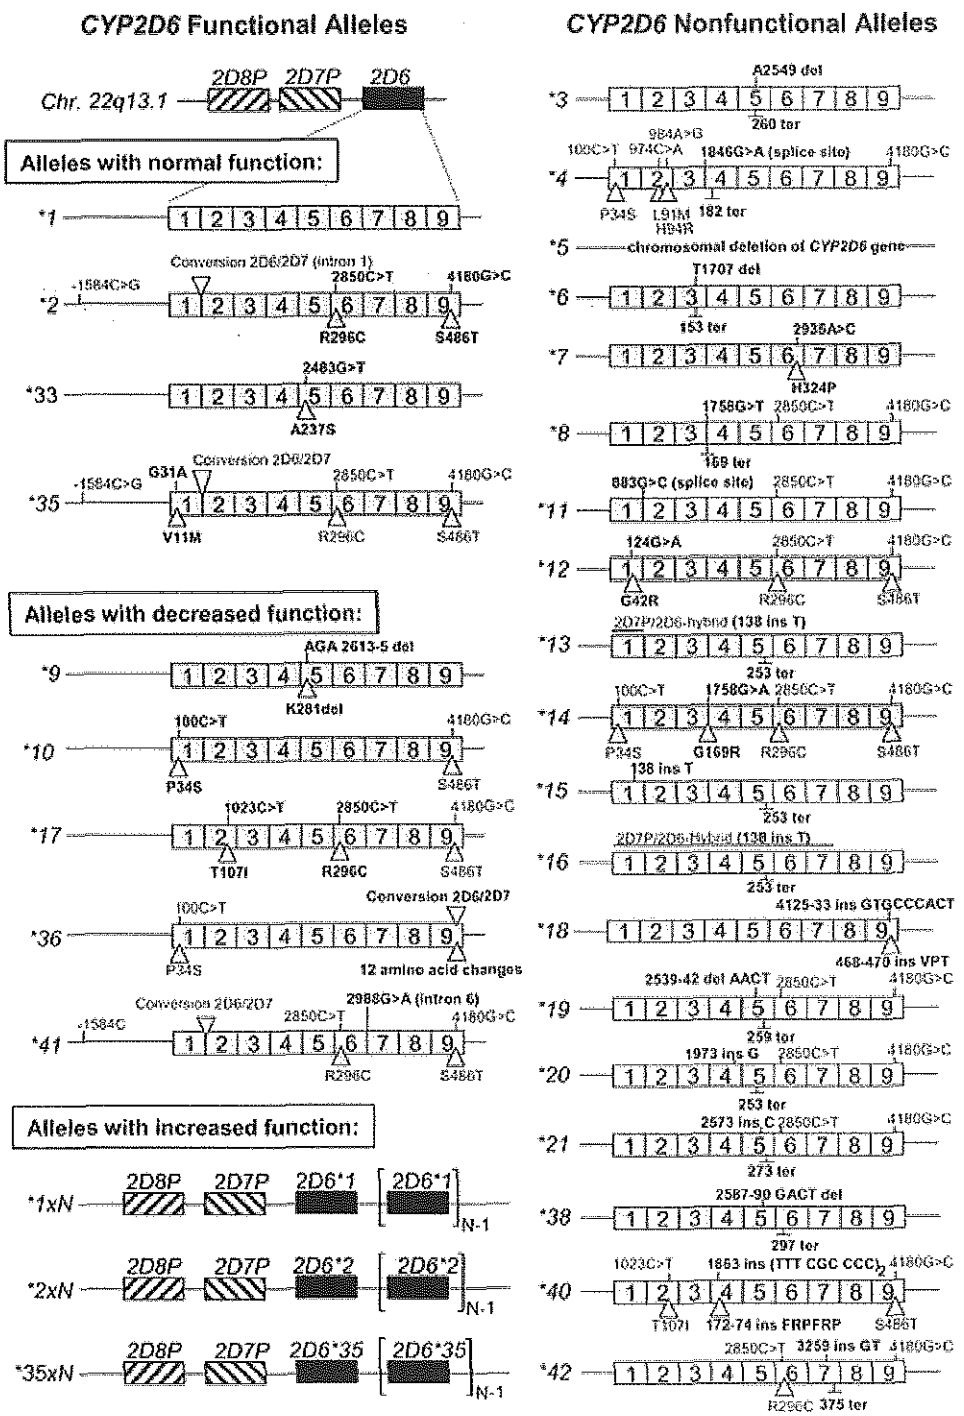

Figure 43-5 Structure of functional and nonfunctional *CYP2D6* alleles. Only alleles with available phenotypical information are shown. The 9 exons are indicated by numbered boxes with DNA polymorphisms indicated on top (*del*, deletion, *ins*, insertion). Predicted amino acid changes and translation termination *(ter)* codons are indicated below. Open reading frames are indicated by shaded boxes. Silent mutations and some promoter and intronic polymorphisms and alleles with uncertain function are not shown. *(From Zanger UM, Raimundo S, Eichelbaum M. Cytochrome P450 2D6: overview and update on pharmacology, genetics, biochemistry. Naunyn Schmiedebergs Arch Pharmacol 2004;369:23-37. Reproduced by permission from Springer.)*

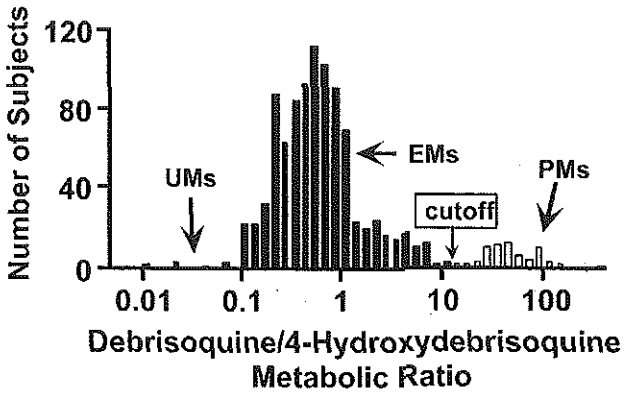

Figure 43-6 Histogram of the "debrisoquine metabolic ratio" in a typical Caucasian population. Metabolic ratios were determined from the concentrations of debrisoquine and 4-hydroxydebrisoquine (metabolite) in a urine specimen collected 8 hours after a 10 mg dose of debrisoquine. The data demonstrate a clear distinction between PM, EM, and UM phenotypes. *(From Caldwell J. Pharmacogenetics and individual variation in the range of amino acid adequacy: the biological aspects. J Nutr 2004;134:1600S-4S; discussion 30S-32S, 67S-72S. Reproduced by permission from the American Society for Nutritional Sciences.)*

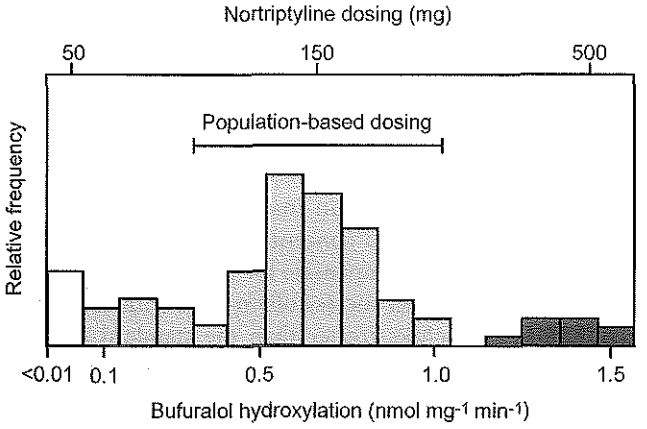

Figure 43-7 Variation in drug metabolism and nortriptyline dosing in the European population, based on cytochrome P450 CYP2D6 activity (hydroxylation of bufuralol). Within the population four phenotypes can be identified: poor metabolizers (PMs), who lack the functional enzyme; intermediary metabolizers (IMs), who are heterozygous for one functional allele or have two partially defective alleles encoding the enzyme; extensive metabolizers (EMs), who have two normal alleles; and ultrarapid metabolizers (UMs), who carry duplicated or multiduplicated functional *CYP2D6* genes. The relative frequency of these phenotypes refers to the European population as a whole. The doses of nortriptyline that are required to achieve therapeutic levels in all phenotypes are given. Despite this variation in metabolizing capability, population-based dosing is used today, and is based on the average plasma levels obtained in a given population for a given dose. *(From Ingelman-Sundberg M. Pharmacogenetics of cytochrome P450 and its applications in drug therapy: the past, present and future. Trends Pharmacol Sci 2004;25:193-200. Reproduced by permission from Elsevier.)*

designed to amplify a large *CYP2D6*-specific region.[50] Small nucleotide changes within this region, including SNPs and smaller insertions/deletions of one or a few bases, are then detected in a second amplification step either designed as a PCR-restriction fragment length polymorphism (RFLP) assay or as an allele-specific PCR without subsequent digestion.[26,38,47,111,122] By evaluating the entire gene, such as through the use of the single-strand conformation polymorphism technique described by Broly et al., both known and unknown mutations in the *CYP2D6* gene can be detected.[16,84] Other technologies used for genotyping *CYP2D6* include real-time PCR methods and microarrays.[22,56,99,101] Gene deletion events necessarily give rise to duplication or multiduplication alleles in a population. The duplicated gene can be either functional, for example *CYP2D6*1, CYP2D6*2,* or *CYP2D6*35* alleles, or nonfunctional, e.g., *CYP2D6*4.* These duplicated genes can be detected either by appropriate RFLP assays, by using one of several available long-product PCR assays, by microarray, or by real-time quantitative PCR of *CYP2D6* in relation to an internal reference gene, such as albumin.[64,82,113,143]

Clinical Applications

CYP2D6 metabolic status can be applied to prescribing of medications, which are known to be transformed by this enzyme. Such medications may be avoided entirely, or the dose can be optimized based on how CYP2D6 affects the drug. For example, many therapeutic drugs are administered as prodrugs. Prodrugs must be metabolized to the active principle to elicit the desired therapeutic effect. An example is codeine, an alkaloid obtained from opium or prepared from morphine by methylation. Codeine must be activated, through metabolism mediated primarily by CYP2D6, to morphine to produce analgesia. Therefore, a CYP2D6 PM could not activate codeine like an EM would, and may not experience analgesia with standard doses. Thus a PM may be best served clinically by selecting a different analgesic agent. An IM is likely to require higher doses of codeine than an EM, and a UM may require lower doses of codeine than an EM.

Most drugs, however, are inactivated by CYP2D6. For example, nortriptyline (NT) and other antidepressant medications are inactivated by CYP2D6. A CYP2D6 PM requires lower doses of NT than an EM to produce similar serum concentrations of active drug (see Figure 43-7). For the purpose of applying a *CYP2D6* genotype to clinical practice, homozygosity or compound heterozygosity for *CYP2D6* PM alleles is consistent with a PM phenotype. The presence of a single PM allele may lead to either an EM or an IM phenotype. Individuals with a PM phenotype have been successfully treated by reducing the dose of antidepressant medications that are inactivated by CYP2D6 by 40% to 80%.[70] Another example is provided by metoprolol succi-

nate, used as a treatment for hypertension and angina pectoris. Therapeutic effect of this agent is proportional to serum concentrations, and striking differences in serum levels are observed with CYP2D6 PM and EM individuals following a single dose of metoprolol.

In contrast to decreased metabolism, increased metabolism of an active drug to an inactive metabolite in UMs results in subtherapeutic concentrations of active drug at standard dosages. To compensate for increased metabolism, UM subjects have been successfully treated with megadoses (twofold to twelvefold greater than the standard dose) of some drugs that are inactivated by CYP2D6 to obtain therapeutic efficacy.[70] Because most drugs act through multiple mechanisms that may or may not relate to the concentration of parent and/or metabolites, high-dose therapy may be associated with unrecognized risks. For example, potentially toxic metabolites may accumulate as a result of UM status and may lead to ADRs. Thus individuals with UM phenotypes may be best served by selecting therapeutic medications that are metabolized by an alternate (non-CYP2D6) route.[76]

CYTOCHROME P450 2C19 (CYP2C19)

CYP2C19 is a member of the CYP2C family, which includes CYP2C8, CYP2C9, CYP2C18, and CYP2C19 of which only *CYP2C9* and *CYP2C19* exhibit substantial genetic variability. Although substrate overlap between the family members exists, CYP2C19 is specifically associated with the 4′-hydroxylation of the S-enantiomer of the anticonvulsant mephenytoin and was originally named mephenytoin hydroxylase.[27] CYP2C19 is a Phase I enzyme for the metabolism of a number of other therapeutic drugs, including citalopram, diazepam, omeprazole, propranolol, and proguanil (see Table 43-3).[110] Like the CYP2D6 isoenzyme, specific genetic variants of *CYP2C19* lead to poor and intermediate metabolizer—PM and IM—phenotypes with respect to a number of common therapeutic drugs. In contrast to the debrisoquine polymorphism, the UM phenotype has not been characterized for this enzyme, though its existence has been postulated.

Genotype to Phenotype

At least 20 allelic variants of *CYP2C19* have been described.[5,17] The EM phenotype has historically been composed of both the homozygous and heterozygous genotypes. The PM phenotype is inherited in an autosomal recessive manner.[17] Like the *CYP2D6* polymorphisms, there are significant interethnic differences in the prevalence of the CYP2C19 PM phenotype. The PM phenotype occurs in 2% to 5% of Caucasian and Black Zimbabwean Shona populations, and 10% to 23% in Asian populations.[142]

Table 43-4 lists *CYP2C19* polymorphisms with the nucleotide change, amino acid changes, and associated enzyme activity phenotype. The principal genetic variant in PMs of S-mephenytoin is *CYP2C19*2,* arising from a 681G>A, which results in a splicing defect and essentially no enzyme activity. The second most common *CYP2C19* allele *(CYP2C19*3)* associated with the PM phenotype results from a single nucleotide substitution 636G>A, which produces a premature stop codon and no active enzyme product.[28,29,98] The allele frequency of *CYP2C19*2* is reported as 32% in East Asians and 71% in Polynesians (Vanuatu), and is approximately 15% in Caucasians and African-Americans. The allele frequency of *CYP2C19*3* is reported as 6% to 10% in East Asians, 13.3% in Polynesians, and <1% among Caucasians. Differences in the incidence of the *CYP2C19*5* polymorphism affecting the S-mephenytoin among ethnic populations have been described.[10,61] Additional alleles, *CYP2C19*4, *6, *8, *9, *10,* and **12* may also contribute to the PM phenotype or have markedly reduced activity toward S-mephenytoin.[6,138]

Testing

Genotyping tests based on PCR-amplification and restriction endonuclease digestion have been developed for detection of polymorphic *CYP2C19* variant alleles. A genotyping strategy including *CYP2C19*2, *3, *4, *5A,* and **5B* for identification of the PM phenotype was associated with a sensitivity of nearly 100% in Chinese and 92% in Caucasian populations.[61] Because the PM phenotype was thought to occur only when both alleles are affected, an initial screening approach incorporating the *CYP2C19*2* and *CYP2C19*3* alleles, with additional testing for the *CYP2C19*4, *5,* and **6* alleles for heterozygous subjects, has also been described. However, this philosophy has come into question given recent findings of the significance of heterozygosity for one inactive *CYP2C19* allele.[14] Recent advances in multiplexed PCR with multiple detection technologies and other technologies, such as pyrosequencing and arrays, will make it possible to screen simultaneously for many alleles in this gene.[107]

Clinical Applications

The proton pump inhibitor omeprazole is primarily inactivated by the CYP2C19 enzyme, and thus its metabolism is subject to this genetic polymorphism (see Figure 43-8). The homozygous variant subjects had 100% cure of upper gastrointestinal (GI) ulcers after omeprazole-based therapy versus 65% and 25% for heterozygous and homozygous wild-type patients, respectively. Studies have demonstrated greater effectiveness of single dose level omeprazole for management of *Helicobacter pylori* infection and peptic ulcer in subjects with one or more *CYP2C19* PM alleles. This is thought to be because of greater exposure to a therapeutic compound in PMs and IMs. However, using triple therapy with rabeprazole, amoxicillin, and clarithromycin, *H. pylori* antimicrobial susceptibility was shown to be a more important factor than *CYP2C19* genotype.[96] No dose adjustments have been proposed to adjust for *CYP2C19* genotype. However, gene-gene interactions may indicate a need to test for genetic variation in more than one gene to guide therapy.

Multigene studies have shown that interleukin (IL)-1β genetic polymorphism, although not an independent factor in treatment outcome, influences the impact of the *CYP2C19* genotype on the cure rate of 1-week triple therapy for *H. pylori* infections.[125]

The antimalarial prodrugs proguanil and chlorproguanil require CYP2C19-dependent bioactivation for therapeutic efficacy.[137] A clear gene-dose effect has been observed for the oxidation of proguanil to cycloguanil and 4-chlorophenylbiguanide.[59] Clinical response has been shown to be affected in CYP2C19 PM individuals.

Currently the most common reason for genotyping *CYP2C19* is to explain inappropriate response to antidepressant medications. For example, CYP2C19 is the primary enzyme responsible for converting amitriptyline (AT) to its active metabolite NT. Monitoring serum or plasma concentrations of both AT and NT as a sum is used to guide AT therapy.[79,106] However, the utility of *CYP2C19* genotyping for this application is somewhat controversial. Using a quantitative gene dose model, it was found that *CYP2D6* but not *CYP2C19* genotyping is most useful in AT therapy based on the fact that *CYP2C19* polymorphisms alter the ratio of AT to NT, but not the sum of the two.[120] The model was derived in a Caucasian population, whereas *CYP2C19* PMs are much more common in Asian populations.[117] CYP2D6 is also thought to be more important than CYP2C19 for newer antidepressants.[46] However, genotyping *CYP2C19* becomes very important for a CYP2D6 PM and is proposed to be important for additional antidepressants such as doxepine, fluoxetine, and moclobemide.

Because of the potential overlap in substrate specificity among the CYP2C family, genotyping both *CYP2C19* and *CYP2C9* may be useful clinically as well. Optimal dosing of the anticonvulsant drug phenytoin can be predicted by testing for variation in *CYP2C9*, *CYP2C19*, and *MDR1*, which encodes the p-glycoprotein.[67] CYP2C9 is estimated to contribute to 90% of phenytoin metabolism, and CYP2C19 is thought to contribute to 10% of phenytoin metabolism in persons with EM phenotypes for both enzymes.[39] In patients who are CYP2C9 PM, CYP2C19 is the primary route of

phenytoin elimination, and hence the importance of testing for CYP2C19 increases.[83]

Cytochrome P450 2C9 (CYP2C9)

CYP2C9 is a member of the CYP2C family, which includes CYP2C8, CYP2C9, CYP2C18, and CYP2C19—of which *CYP2C9* and *CYP2C19* exhibit substantial genetic variability. Although substrate overlap between the family members exists (see Table 43-3), CYP2C9 is specifically associated with metabolism of the sulfonylurea hypoglycemic agent tolbutamide. CYP2C9 is involved in the metabolism of approximately 16% of therapeutic compounds.[110,114] At least 12 allelic variants have been described in this gene and are shown in Table 43-5.[5]

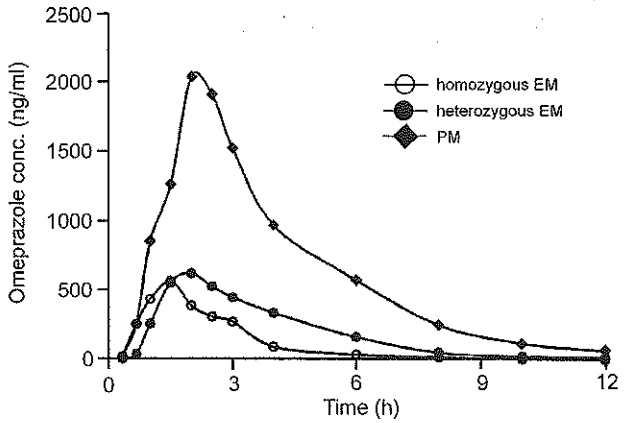

Figure 43-8 Mean plasma concentration-time profile of omeprazole after oral administration of 40 mg omeprazole (in the form of 2 × 20-mg Losec capsules) to 27 male Chinese subjects phenotyped for CYP2C19 activity with mephenytoin. Plasma concentrations of omeprazole were significantly higher in PMs (◆) than in homozygous EMs (○) or heterozygous EMs (●). In addition, the elimination half-life for omeprazole was 2.3-fold greater in PMs than in EMs ($p < 0.001$). *(From Yin OQ, Tomlinson B, Chow AH, Waye MM, Chow MS. Omeprazole as a CYP2C19 marker in Chinese subjects: assessment of its gene-dose effect and intrasubject variability. J Clin Pharmacol 2004;44:582-9. Reproduced by permission from Sage Publications, Inc.)*

Genotype to Phenotype

Two variant alleles of *CYP2C9* (*CYP2C9*2* and *CYP2C9*3*) account for most CYP2C9 PM phenotypes.[98] The allelic frequency of *CYP2C9*2* has been reported as 8% to 19% in Caucasians, and 1% to 4% in African-Americans and Canadian Native Indians. This allele has not been detected in Asians. The allelic frequency of *CYP2C9*3* has been reported as 6% to 10% in Caucasians, 1.7% to 5% in Asians, and 0.5% to 1.5% in African-Americans. Homozygosity for the *CYP2C9*3* allele is relatively rare in Caucasians (1% to 2%).[115] Studies in vitro have shown that the protein produced by the *CYP2C9*3* variant is less than 5% as efficient as the *CYP2C9*1* allozyme, whereas *CYP2C9*2* shows about 12% of *CYP2C9*1* allozyme activity in most assays. *CYP2C9*2* and *CYP2C9*3* alleles result in PM in the homozygous state, and IM phenotypes when heterozygous. Two additional alleles, found in African-Americans, have been described, *CYP2C9*5* and *CYP2C9*6*. The *CYP2C9*6* in a homozygous individual was shown to contribute to an extremely long phenytoin elimination, with a half-life approximately 5.8 times longer than *CYP2C9* extensive metabolizers.[68] The *CYP2C9*8* allele has been shown in vitro to have greater activity than the wild-type enzyme, demonstrating 175% tolbutamide hydroxylase activity of recombi-

TABLE 43-5 *CYP2C9* Alleles

nant wild-type (see Figure 43-9). It was previously believed that no UM phenotypes existed for the *CYP2C9* gene; however, *CYP2C9*8* may dispel that notion.[9]

Testing

There have been several published protocols for detecting variants in this gene. Many of the clinically important polymorphisms are amenable to PCR-RFLP, allele-specific primer extension (ASPE), and microarrays. Recently, multiplexed assays have been described that screen the entire gene for many variants for little additional cost above testing for a subset of alleles.[107,121]

Clinical Applications

Examples of therapeutic compounds metabolized by CYP2C9 include nonsteroidal antiinflammatory (NSAID) medications, irbesartan, naproxen, and fluvastatin (see Table 43-3). Proposed dose adjustments based on phenotype have been published for CYP2C9 drug substrates such as warfarin, glipizide, tolbutamide, and phenytoin.[55,80]

An illustration of the effects of decreased CYP2C9 activity on a therapeutic compound is the effect on anticoagulation therapy with S-warfarin. Individuals with the *CYP2C9*2* and *CYP2C9*3* polymorphisms have impaired metabolism of warfarin and thus increased plasma concentrations of the drug with standard dosing. As illustrated in Figure 43-10, standard 5 mg/day maintenance dosing of warfarin in subjects with CYP2C9 genetic variants can lead to an excessive warfarin exposure, resulting in an exaggerated anticoagulant response. The clinical impact of *CYP2C9* polymorphism includes increased risk of serious or life-threatening bleeding complications and increased time to achieve a stable INR if the dosages are not lowered to accommodate their reduced metabolizer phenotype.

Inherited impairment of CYP2C9 activity may also increase the risk for severe ADRs after NSAID use. For example, Martinez et al found that the frequency of *CYP2C9* variant alleles was higher in bleeding patients, with a significant trend to higher risk with increasing number of variant alleles ($p = 0.02$).[87]

N-Acetyl Transferases (NAT1 and NAT2)

The N-acetyl transferase (NAT) polymorphism is one of the earliest pharmacogenetic targets recognized and characterized. NATs are Phase II enzymes that catalyze the transfer of an acetyl moiety from acetyl-CoA to homocyclic and heterocyclic arylamines and hydrazines. Substrates include drugs, carcinogens, toxicants, and possibly endogenous compounds. Slow metabolizer phenotypes, which may affect up to 90% of some populations, are manifested by changes in protein expression, protein stability, and enzyme kinetics.

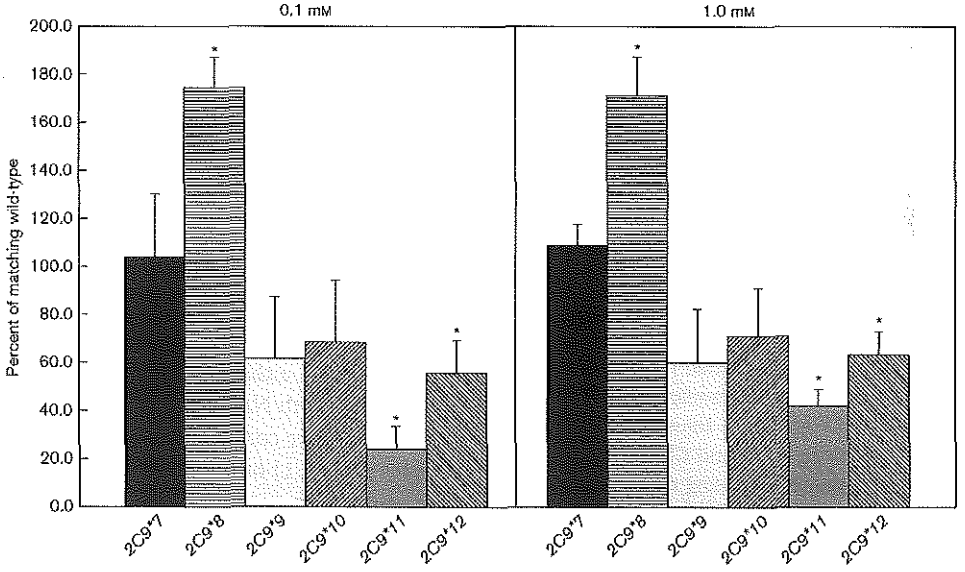

Figure 43-9 Tolbutamide hydroxylase activity of recombinant wild-type *(CYP2C9*1)* and new variant *CYP2C9* alleles. *CYP2C9* alleles were expressed in *Escherichia coli* and partially purified. For each variant allele, three individual preparations (two preparations for *CYP2C9*7*) were purified from bacteria simultaneously with wild-type. Each preparation was assayed in triplicate at high (1 mmol/L) and low (0.1 mmol/L) substrate concentrations on the same day. Values are given as a percentage of enzymatic activity of the wild-type allele. *Significantly different from *CYP2C9*1* protein activity ($P < 0.05$). *(From Blaisdell J, Jorge-Nebert LF, Coulter S, Ferguson SS, Lee SJ, Chanas B, et al. Discovery of new potentially defective alleles of human CYP2C9. Pharmacogenetics 2004;14: 527-37. Reproduced by permission from Lippincott Williams & Wilkins.)*

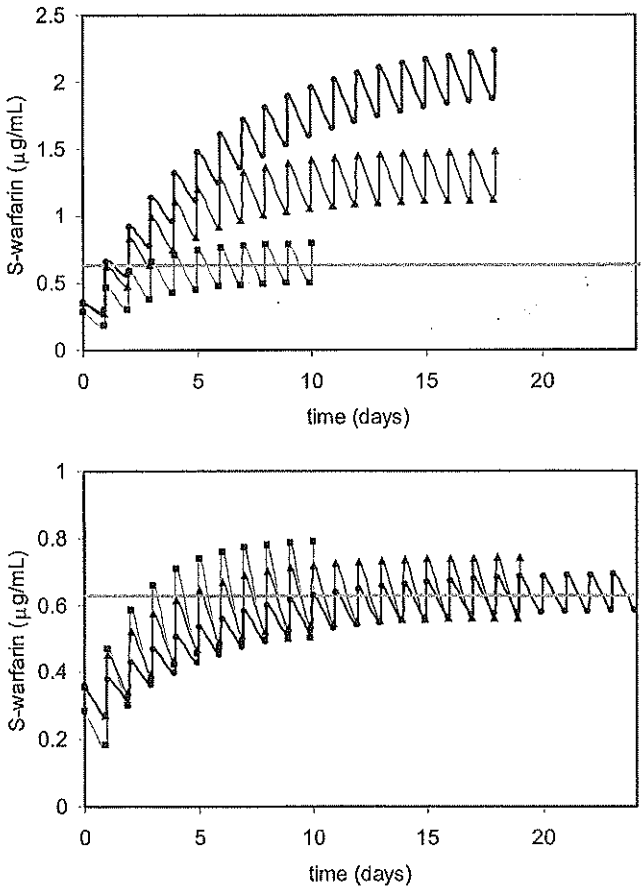

Figure 43-10 Model of warfarin dosing based on *CYP2C9* genetics. In both panels, the conventional therapeutic S-warfarin target level is shown (horizontal line) for reference. The top panel depicts a model for warfarin therapy in patients using the standard 5 mg/day dose with all genotypes. *CYP2C9*1/*1* individuals (■) on 5 mg, twice per day would attain stable and therapeutic serum S-warfarin levels (0.68 μg/mL) in approximately 4 days. *CYP2C9*1/*2* (▲) and *CYP2C9*1/*3* (●) individuals on the same 5-mg dose are modeled to attain S-warfarin serum levels that are both too high by the second day and if not adjusted would lead to overanticoagulation. *CYP2C9*1/*2* patients would stabilize at twice therapeutic serum levels after 10 to 12 days, but *CYP2C9*1/*3*, if not adjusted, would continue to rise. The bottom panel depicts serum S-warfarin level outcomes for a dosing regimen modified for genotype. All patients would be given the standard 5-mg dose twice, then switched to a *CYP2C9* genotype adjusted dose for maintenance, *CYP2C9*1/*2* receiving 3 mg and *CYP2C9*1/*3* receiving 1.5 mg. This genotype adjusted dosing could result in *CYP2C9*1/*2* and *CYP2C9*1/*3* achieving stable, therapeutic S-warfarin levels in 10 days, thereby avoiding overanticoagulation in these individuals. *(Adapted from Linder MW, Looney S, Adams JE III, Johnson N, Antonino-Green D, Lacefield N, et al. Warfarin dose adjustments based on CYP2C9 genetic polymorphisms. J Thromb Thrombolysis 2002;14:227-32. Reproduced by permission from Springer.)*

Several good reviews on the NAT polymorphisms have been published.*

Genotype to Phenotype

The first NAT polymorphism, attributed to an enzyme originally called "isoniazid transacetylase," was recognized in the 1950s with isoniazid (L-isonicotinyl hydrazide), a drug used to treat tuberculosis.[12] Population studies revealed a bimodal distribution in plasma and urine levels of the N-acetylated isoniazid metabolite. Concentration of the parent drug was highly correlated with the prevalence of toxic symptoms, including hepatotoxicity and a painful and progressive peripheral neuropathy that affected up to one third of Caucasian and African-American patients. From this initial work, patients were phenotypically described as "fast acetylators" or "slow acetylators." Slow acetylators excrete large amounts of the parent drug relative to the acetylated metabolite when compared with fast acetylators. Family studies identified a strong genetic linkage of this phenotype and suggested that the phenotype was inherited as an autosomal recessive trait.[32,132]

Studies with additional substrates for NAT demonstrated that the phenotype was not relevant to all substrates. For example, the NAT phenotype was clearly recognized for arylamines such as isoniazid, some sulfonamides, amrinone, dapsone, procainamide, caffeine, and clonazepam. The phenotype was not observed with other arylamine substrates such as p-aminobenzoate (PABA) and p-aminosalicylate (PAS). A folate catabolite, p-aminobenzoylglutamate, is the only endogenous NAT substrate proposed.[97] However, *NAT2* knock-out and *NAT1* and *NAT2* double knock-out mice do not express phenotypical abnormalities, suggesting that these enzymes are not required for development or function.[123]

In 1965 it was proposed that two isoforms of NAT, later named NAT1 and NAT2, were responsible for the differences in phenotypes observed previously. Of the two proposed isoforms, NAT2 correlated best with the isoniazid (polymorphic) phenotype.[63] It was also suggested that the fast and slow acetylator phenotypes were caused by differences in expression rather than in the enzyme kinetics. Subsequently, it was found that although most substrates exhibit higher specificity for either NAT1 or NAT2, most substrates have affinity for both NAT1 and NAT2 (Table 43-6). Nonetheless, substrates were commonly classified as monomorphic (substrates of NAT1) or polymorphic (substrates of NAT2) until the mid-1990s.

NAT1, which is now recognized to be polymorphic, is extremely unstable and therefore more difficult to study than NAT2. Because of stability differences and overlapping substrate specificity, tissue localization studies for the NATs have been challenging. It is now recognized that both NAT1 and NAT2 are expressed throughout the GI tract, and in the lung, bladder, ureter, and liver.[43,135]

TABLE 43-6 NAT Substrates

Drugs	Potential Carcinogens or Toxicants
Aminoglutethimide	p-aminobenzoic acid (PABA)*
Amonafide	4-aminobiphenyl
Amrinone	2-aminodipyrido[1,2-a:3′2′d]-imidazole (Glu-P-2)
Caffeine	2-aminofluorene*
Clonazepam	2-amino-3,8-dimethylimidazo [4,5-f]quinoxaline (MeIQx)†
Dapsone	2-amino-3-methyl-imidazo [4,5-f]quinoline (IQ)†
Dipyrone	3-amino-1-methyl-5H-pyrido [4,3-b]indole (Trp-P-2)
Endralazine	p-aminosalicylic acid (PAS)*
Hydralazine	Benzidine
Isoniazid	3,4-dichloroaniline
Prizidilol	3,2′-dimethyl-4-aminobiphenyl
Prizidilol	B-naphthylamine
Procainamide†	p-phenetidine
Sulfonamides:†	
Sulfadiazine	o-toluidine†
Sulfadoxine	p-toluidine
Sulfamethazine	
Sulfamethoxazole	
Sulfapyridine	
Sulfasalazine

Metabolic activation and deactivation of arylamine carcinogens by recombinant human NAT1 and polymorphic NAT2 acetyltransferases. Carcinogenesis 1993;14:1633-8.
*Strong selectivity for NAT1 based on NAT1/NAT2 activity (nmol/min/U) ratio >300.
†Similar selectivity for NAT1 and NAT2 based on NAT1/NAT2 activity ratio <15.

There are three human NAT genes that are mapped to chromosome 8p22 and were first cloned in 1990. The *NAT1* and *NAT2* genes share 87% nucleotide sequence identity and 81% amino acid sequence identity. The third gene *NATP* is thought to be a noncoding pseudogene. Each of the NAT genes has an intronless open reading frame exon of 870 bp and codes for 290 amino acids.[11,13,127,128] Many variant alleles have been described for both NAT1 (Table 43-7) and NAT2 (Table 43-8). A consensus nomenclature was published in 1995 and updated in 2000.[4,53,128] The wild-type alleles, although somewhat arbitrary due to high population frequencies of multiple alleles, are *NAT1*3* and *NAT2*4*. For *NAT2*, former common nomenclature included M1 for *NAT2*5A*, M2 for *NAT2*6A*, and M3 for *NAT2*7A*. The *NAT2*5, *6, *7, *13,* and **14* alleles are thought to account for more than 99% of slow acetylator phenotypes. The *NAT1*10* is the most common variant *NAT1* allele in many human populations, but the phenotype-genotype relationship is not well defined. Other *NAT1* alleles that appear rare in humans produce enzymes with definitively reduced activity, and potential clinical implications include *NAT1*14, 15, 17, 19,* and *22*.[44,51,77,95,131]

The three-dimensional crystal structures of the two NAT isoenzymes have been determined. Structural studies suggest that the active catalytic site of the NATs involves three amino acids, a cysteine residue juxtaposed with histidine, and aspartate residues. The C-terminus is responsible for substrate specificity.[118] The acetylation reaction occurs through a classical two-step mechanism, where an acetyl moiety is transferred from acetyl CoA to NAT and then from NAT to the arylamine to form an arylamide. As shown in Figure 43-11, *N*-acetylation, thought to primarily generate nontoxic stable products, is mediated by both NAT1 and NAT2. *O*-Acetylation of cytochrome P450 *N*-hydroxylated products is also mediated by both NAT1 and NAT2 and is thought to generate reactive products that may spontaneously decompose to form nitrenium ions. Nitrenium ions are electrophiles that may subsequently bind covalently to intracellular nucleophiles such as DNA or proteins and be responsible for cell death, mutagenesis, or other toxicities. An intramolecular *N,O*-acetyltransfer reaction is mediated primarily by NAT1 and also may lead to reactive products. Other enzymes that may interrupt or contribute to these reactions include CYP1A2, prostaglandin H synthase, UDP-glucuronosyltransferase, and sulfotransferase.[45,136]

Testing

NAT2 slow acetylators are common in many populations: approximately 83% of Egyptians; 40% to 60% of Caucasians, Europeans, and African-Americans; 10% to 30% of Asians; and 5% of Canadian Eskimos.[48,95] *NAT1*10* allele frequency is reported high in a Japanese population (62.3%) compared with a European population (29%), but further efforts are required to fully elucidate the population frequencies of the various *NAT1* alleles currently identified.[66] Variables that affect NAT phenotyping include the substrate or probe drug used, age and disease status of the individual, medications, dietary factors such as ingestion of well-cooked meat, and lifestyle factors such as cigarette smoking or occupational exposure to NAT substrates.

The most common method of NAT1 phenotyping is to measure enzyme activity in isolated lymphocytes using PABA, PAS, or another relatively specific NAT1 substrate. However, phenotyping in vivo with a probe drug has also been performed.[52,60,94] The most common phenotyping method for NAT2 is to administer a probe drug and evaluate ratios of parent/metabolite or metabolite-A/metabolite-B concentrations. Probe drugs may include any relatively specific NAT2 substrate, the most common and safe of which is

Modified from references 4, 44, 45, and 51.

caffeine. One published phenotyping method involves administration of 200 mg caffeine following an overnight fast. Urine is collected 4 and 5 hours later. The 5-hour specimen is analyzed for caffeine metabolites 5-acetylamino-6-formylamino-3-methyluracil (AFMU) and 1-methylxanthine (1X). Cutoffs for acetylator phenotypes are based on the ratio of AFMU/1X. Considering a bimodal distribution of acetylators, a ratio of less than 0.66 is used to define slow acetylators. Because a trimodal distribution has been described and may be of interest, a ratio higher than 3.0 could define "ultrarapid" acetylators; a ratio between 0.66 and 3.0 would define a classic rapid acetylator or in a trimodal distribution, an "intermediate" acetylator phenotype.[48,72]

Genotyping can predict NAT phenotype quite well, with concordance of 90% to 100% for *NAT2*. For *NAT2*, an example of the phenotype-genotype relationship published by Cascorbi et al in 1995 with a population of unrelated Germans is depicted by histogram (Figure 43-12). Only 6.7% of genotypes did not agree with the phenotypes in this study. Methods have primarily employed PCR-RFLP, but real-time PCR and other allele-specific detection methods have also been described.[8,21,37,54,95]

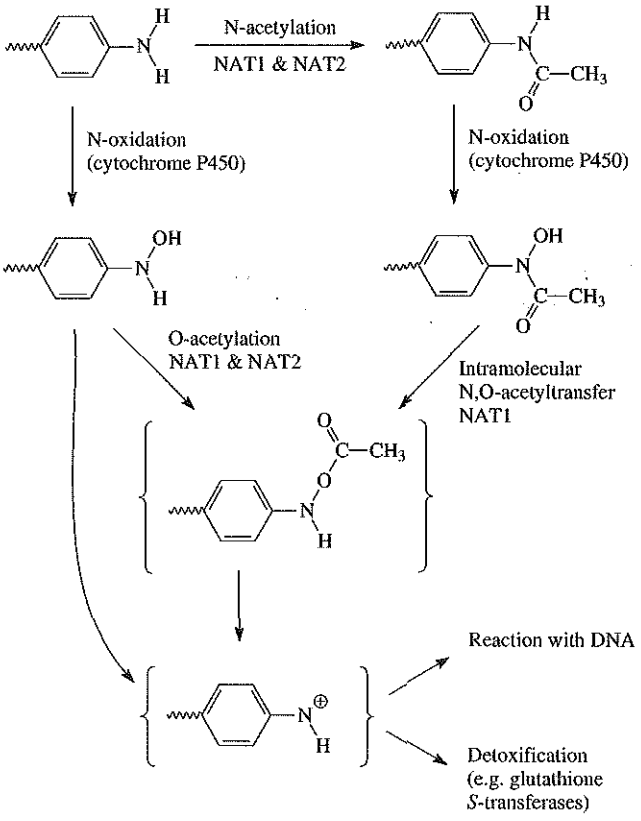

Figure 43-11 Schematic view of the role of NAT enzymes in the metabolism of aromatic amines. N-acetylation might be a detoxification reaction in a number of cases; however, after N-hydroxylation of aromatic amines (e.g., by CYP enzymes), NAT enzymes can bioactivate these intermediates by either *O*-acetylation or intramolecular *N,O*-acetyltransfer, leading to the formation of nitrenium ions, which might react with DNA or alternatively be detoxified by, for example, GST enzymes. Importantly, it is shown that a number of other biotransformation enzymes are also involved in the metabolism of aromatic amines as well. *(Redrawn from Wormhoudt LW, Commandeur JNM, Vermeulen NPE. Genetic polymorphisms of human N-acetyltransferase, cytochrome P450, glutathione-S-transferase, and epoxide hydrolase enzymes: relevance to xenobiotic metabolism and toxicity. Crit Rev Toxicol 1999;29:59-124. Reproduced by permission from Taylor and Francis, Inc.)*

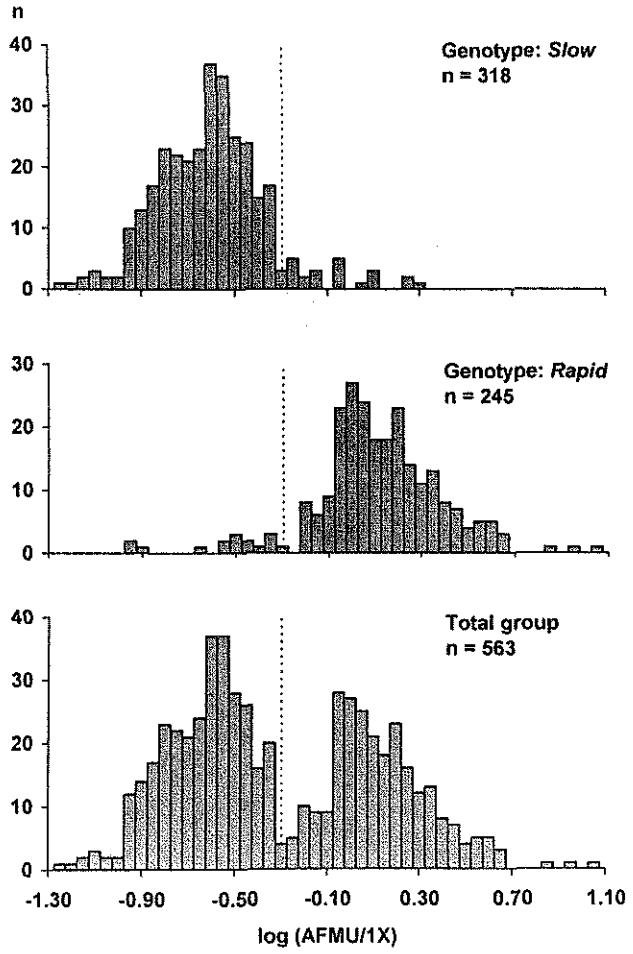

Figure 43-12 Histogram of NAT2 phenotypical activities as obtained by the caffeine test: 5 hr urine collection obtained after administration of caffeine, and analyzed for caffeine metabolite concentrations. Values represent the logarithmically transformed ratio of metabolites 5-acetylamino-6-formylamino-3-methyl-uracil (AFMU) and 1-methylxanthine (1X). From the distinct biomodal distribution an antimode of log(0.50) = –0.30 was obtained *(dotted line). (From Cascorbi I, Drakoulis N, Brockmoller J, Maurer A, Sperling K, Roots I. Arylamine N-acetyltransferase (NAT2) mutations and their allelic linkage in unrelated Caucasian individuals: correlation with phenotypical activity. Am J Hum Genet 1995;57:581-92. Reproduced by permission from the University of Chicago Press.)*

Clinical Applications

NAT status has been implicated in propensity for experiencing ADRs and, unlike the CYPs and TPMT, NAT status has been associated with risk of disease, including immunological disorders—such as rheumatoid arthritis and systemic lupus erythematous—and several cancers, particularly bladder, lung, gastric, and colorectal. NAT substrate exposure can be related to cigarette smoking, some medications, occupational exposure (cooking, dye, and rubber industries), and several environmental toxicants (see Table 43-6). NAT testing may be important for individuals at high risk of exposure to NAT substrates or in whom adverse reactions to probable NAT substrates have been experienced.

Neither genotyping nor phenotyping methods are widely available for clinical testing. However, research involving the genotyping or phenotyping of NAT polymorphisms has significantly impacted pharmacotherapy with NAT substrates and drug development. With isoniazid, the recognition of distinct phenotypical differences that led to ADRs furthered research into the pathological mechanisms. For example, the neuropathic consequences are linked to pyridoxine deficiency, which can be avoided by co-administration of pyridoxine to all patients. Because rapid acetylators are less likely to respond to the conventionally administered dose, the iso-

TABLE 43-9 Additional Pharmacogenetic Targets Being Studied

Polymorphic Gene(s)	Protein(s)	Drugs or Drug Classes Possibly Affected by Variants
ACE	Angiotensin converting enzyme	ACE inhibitors
ABCB1	MDR1, p-glycoprotein	Immunosuppressants, antiretrovirals, anticonvulsants, cardiac glycosides
ADD1	Adducin 1 (α)	Diuretics
ADRB1 and 2	β-Adrenergic receptor	β-Agonists, β-blockers
AGT and AGTR1	Angiotensinogen and receptor	Antihypertensives
ALOX5	Arachidonate 5-lipoxygenase	Leukotriene receptors, 5-lipoxygenase inhibitors
APOE	Apolipoprotein E	Statins, acetylcholinesterase inhibitors (Alzheimer's therapeutics)
BCHE	Butyrylcholinesterase	Succinylcholine
BDKRB2	Bradykinin receptor B2	ACE inhibitors
CETP	Cholesteryl ester transfer protein	Statins
COMT	Catechol O-methyltransferase	Antipsychotics
CYP1A2, 2B6, 1E, 3A	Cytochrome P450 drug metabolizing enzymes	Several; >50% of all therapeutic drugs
DRD2, 3, and 4	Dopamine receptor	Antipsychotics
ERα	Estrogen receptor α	Hormone replacement therapy
FCGR3A	FcγRIIIa receptor	Rituximab
GNB3	Guanine nucleotide binding protein	Antipsychotics, antidepressants
GRIN2B	Glutamate receptor	Antipsychotics
GST	Glutathione S-transferases	Cancer chemotherapeutics
HERG, KvLQT1, Mink, MiRP1	Ion channels involved in congenital long-QT syndrome	Antibiotics, quinidine
HLA-B	Major histocompatibility complex class I-B	Antiretrovirals
HTR2A	Serotonin (5-HTT) receptor	Antipsychotics, antidepressants
IL10	Interleukin 10	Prednisone and antivirals
LIPC	Hepatic lipase	Statins
MTHFR	5,10-Methylene-tetrahydrofolate reductase	Methotrexate
SLC6A3	Dopamine transporter	Antipsychotics, antidepressants
SLC6A4	Serotonin transporter	Antipsychotics, antidepressants
TNF	Tissue necrosis factor	Immunosuppressants, carbamazepine
TPH1	Tryptophan hydroxylase 1	Antidepressants
TYMS	Thymidylate synthase	5-Fluoruracil
UGT1A1	UDP-Glucuronosyltransferase 1A1	Irinotecan
XRCC1	DNA repair protein XRCC1	Cancer chemotherapeutics

Modified from Evans WE, McLeod HL. Pharmacogenomics—drug disposition, drug targets, and side effects. N Engl J Med 2003;348:538-49; Goldstein DB, Tate SK, Sisodiya SM. Pharmacogenetics goes genomic. Nat Rev Genet 2003;4:937-47.

niazid dosing intervals are changed from once a week to twice per week. For procainamide, determining the acetylator status is accomplished through routine therapeutic drug monitoring of the parent and metabolite, N-acetylprocainamide (NAPA). The dose of procainamide is adjusted based on the parent/metabolite ratio. In the development of amonafide, a chemotherapeutic agent inactivated by NAT conjugation, acetylator-based dosing was defined through clinical trials. Although the drug is no longer in development, it is an example of how pharmacogenetic phenomena can support individualized therapy.

Other Pharmacogenetic Targets and Future Directions

As discussed previously in this chapter, any protein for which the related gene exhibits polymorphism has potential phar-

TABLE 43-10 Pharmacogenetic Targets Involved in Xenobiotic Metabolism and Important in Cancer

Polymorphic Gene Important to Metabolism	Chemotherapeutic Drug Substrates	Carcinogen Substrates

UGT1A1	Irinotecan	

Modified from Brockmoller J, Cascorbi I, Henning S, Meisel C, Roots I. Molecular genetics of cancer susceptibility. Pharmacology 2000;61:212-27; McLeod HL, Papageorgio C, Watters JW. Using genetic variations to optimize cancer chemotherapy. Clinical Advances in Haematology and Oncology 2003;1:107-11.

macogenetic implications. With relationship to drug metabolism, additional CYPs including *CYP1A2, CYP2B6, CYP2E1, CYP3A4*, and *CYP3A5* have also been proposed as important pharmacogenetic targets. Other Phase II enzymes that exhibit marked genetic variability among individuals, particularly the glutathione *S*-transferases, may be clinically important as well. In addition, genetic variation in alcohol dehydrogenase, catechol *O*-methyltransferase, and dihydropyrimidine dehydrogenase is important. The interrelationship of these various enzymes as major versus minor, and dependent versus independent mechanisms of metabolism for a single compound will be important to determine the most clinically useful and cost-effective pharmacogenetic testing strategy. Also important will be to gain a better understanding of haplotype relationships and the possible implications of heterozygote variants, for a single gene and combinations of related genes.

Beyond metabolism, pharmacogenetic targets that may become important to TDM and pharmacotherapeutics in general include genes that encode for any protein associated with drug handling, such as drug transporters (e.g., p-glycoprotein and lipoproteins), drug receptors (e.g., dopamine, adrenergic, and serotonin receptors) or effectors (e.g., folate metabolism and catecholamine transporters). Table 43-9 lists examples of pharmacogenetic targets not explicitly discussed in this chapter for which some genotype-to-phenotype relationship has been demonstrated.

Additional studies, particularly prospective and outcome-related, are also required to apply pharmacogenetic findings to the clinic. From an interpretive perspective, more guidelines for dose adjustments need to be established, including consideration of how the dosing recommendations are affected by co-prescribed medications and/or environmental factors. Closer integration of pharmacy professionals with clinical laboratories and clinicians will improve success in pharmacogenetic applications. Commercially available and cost-effective methods for genotyping or phenotyping are also required. The future of pharmacogenetic testing is likely to be driven most by the consumer and by the pharmaceutical providers that promote pharmacogenetic testing, such as in package labeling recommendations. Clinical trials for new pharmaceutical agents are currently considering the benefits of pharmacogenetic testing for individual products.

Complementary to, but separate from TDM, pharmacogenetics or "toxicogenetics" may apply similar concepts to the field of risk stratification, such as for cancer thought to be triggered by environmental or dietary exposure to a wide variety of xenobiotics. Shown in Table 43-10 are some of the genetic targets that have been studied with regard to risk of various cancers and also because of their role in the activation or inactivation of cancer chemotherapeutics.[15] Genes that encode for drug metabolizing enzymes are of most interest for this application as it is through these enzymes that xenobiotics become activated or inactivated. In addition to NAT1, NAT2, and the CYPs discussed previously in this chapter are the glutathione S-transferases (GSTs). At least 16 GSTs have been identified, which are divided into classes designated as Alpha (A), Kappa, Mu (M), Pi (P), Sigma, Theta (T), Zeta, and Omega. The *GSTM1* deficient trait has, for example, been associated with higher risk of lung and bladder cancer.[49] With additional study and validation of these and other genetic markers, preemployment testing to identify individuals with high susceptibility to chemical carcinogens may become important for occupational settings, such as agriculture and manufacturing.

Cancer treatments are of particular interest because of common ADRs. Current chemotherapeutic research includes the drug metabolizing enzymes dihydropyrimidine dehydrogenase (DPYD) and UDP-glucuronosyltransferase (UGT). These enzymes have significant interpatient variability in the metabolism of 5-fluorouracil (5-FU) and irinotecan, respectively.[30,91] *DPYD*2A,* the most common variant allele that leads to a nonfunctional DPYD protein, is caused by a G>A transition. The presence of this allele is correlated with severe toxicity and mortality following treatment with standard doses of 5-FU. Likewise, the *UGT1A1*28* allele has been correlated with irinotecan toxicity.[3] Such pharmacogenetic markers may prove useful for optimizing the pharmacotherapy of cancer.

The field of pharmacogenetics is currently benefiting pharmacotherapeutics by improving dose optimization tools for a select group of medications, such as AZA and 6-MP. Studies suggest that pharmacogenetics tools are potentially useful for dose selection and optimization of many clinically important drugs, particularly those with a narrow therapeutic index (e.g., cancer chemotherapeutics), those which have a narrow opportunity to exert efficacy (e.g., immunosuppressants), those which require weeks or more to determine therapeutic efficacy (e.g., antidepressants), and those which are at high risk for adverse effects and are administered chronically (e.g., lipid lowering). Pharmacogenetics also shows promise in the investigation of ADRs, including postmortem, and for assessing risk for xenobiotic-related conditions, including some cancers.

Cardiac Function

Fred S. Apple, Ph.D., and Allan S. Jaffe, M.D.

Although the heart is an efficient and durable pump, there are a variety of problems that can diminish cardiac function and lead to a variety of abnormal states. One of these problems is heart failure. It and acute ischemic heart disease are the most common diseases that rely on a biochemical diagnosis and thus will be the major focus of this chapter.[7]

The term acute myocardial infarction (AMI) is defined as an imbalance between myocardial oxygen supply and demand resulting in injury to and the eventual death of myocytes. Initially, the population of myocytes was thought fixed; however, it is now thought that the migration of stem cells has the potential at least to replace some of the damaged myocytes. When the blood supply to the heart is interrupted, "gross necrosis" of the myocardium results. Such extensive necrosis is most often associated with a thrombotic occlusion superimposed on coronary atherosclerosis. It is now apparent that the process of plaque rupture and thrombosis is one of the ways in which coronary atherosclerosis progresses and that we only recognize more severe events.[164,165] Total loss of coronary blood flow results in a clinical syndrome associated with what is known as ST segment elevation AMI (STE AMI). Partial loss of coronary perfusion if severe also can lead to necrosis as well—which is generally less severe and is known as NSTEMI (non-ST-elevation myocardial infarction), and other events of still lesser severity may be missed entirely or called angina, which can range from stable to unstable.

In the United States, approximately 700,000 patients suffer from an initial AMI annually and another 500,000 from a recurrent AMI. Coronary heart disease causes 20% of all deaths in the United States and cardiovascular diseases up to 38.5%. About 1.7 million patients are hospitalized each year in the United States with an acute coronary syndrome (ACS). Historically, most deaths caused by ischemic heart disease were acute, but as our therapeutic abilities have increased, the disease is slowly becoming a more chronic one. When deaths occur acutely, they are caused by either ventricular arrhythmias or pump dysfunction and congestive heart failure with or without cardiogenic shock. Death rates are sharply age dependent, both during hospitalization and the year following infarction. In the United States, the yearly economic burden of coronary artery disease (CAD) is in excess of $133.2 billion, more than a third of the total of $368.4 billion due to cardiovascular disease overall.

Before the advent of coronary care units, treatment of AMI was directed almost exclusively toward allowing healing of the infarct. The concept that infarctions evolve over time and that their size can be moderated led to a rethinking of this passive philosophy.[186] We now know that the reestablishment of nutritive perfusion reduces the extent of myocardial injury and is an important determinant of prognosis.[197] Today the management of AMI suggested by most guidelines is aggressive and invasively oriented in the hope of reducing the extent of the myocardial damage and thus improving prognosis.[39a,40,197] In addition, prevention is finally being recognized as a key element in the long-term treatment of patients with atherosclerosis and is included in these guidelines.

BASIC ANATOMY

The average human adult heart weighs approximately 325 g in men and 275 g in women and is 12 cm in length. The heart is a hollow muscular organ, shaped like a blunt cone, and is about the size of a human fist. It is located in the mediastinum, between the lower lobes of each lung, and rests upon the diaphragm. It is enclosed in a sac called the *pericardium.* The cardiac wall is composed of three layers: the *epicardium* (the outer most layer), a middle layer, and an inner layer called the *endocardium.* The heart has four chambers. The two upper chambers are termed the *right* and *left atria,* and the two lower chambers are termed the *right* and *left ventricles* (Figure 44-1). Under normal circumstances, the atria are compliant structures, so that intercavitary pres-

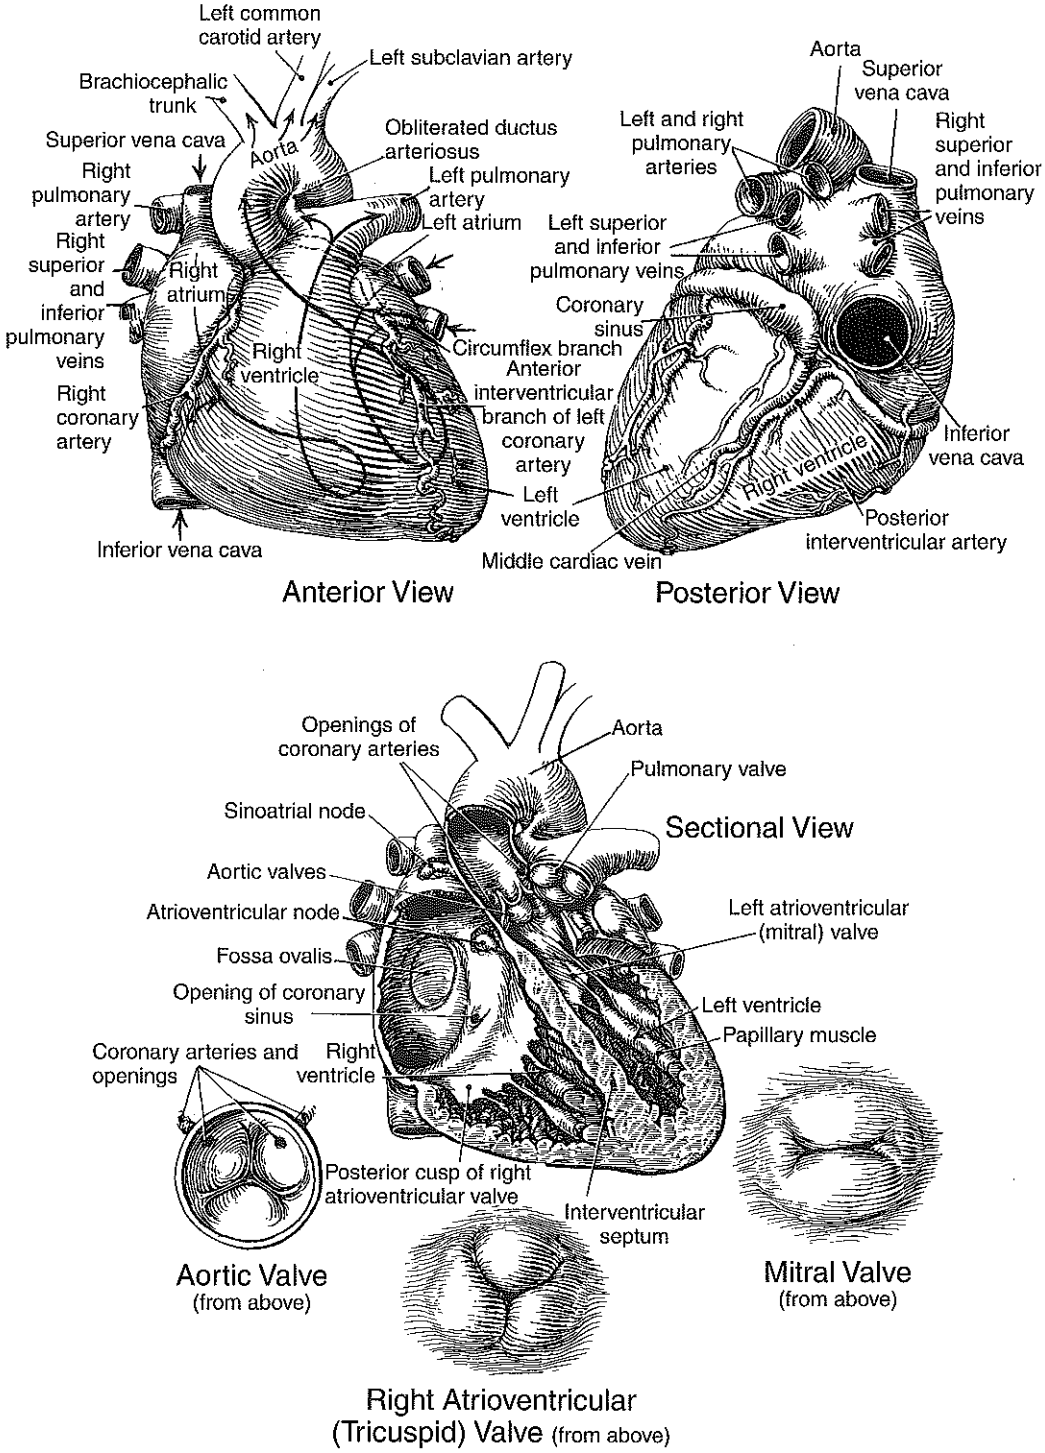

Figure 44-1 Anatomy of the heart. *(From Dorland's Illustrated Medical Dictionary, 30th ed. Philadelphia: WB Saunders Co, 2003:Panel 20.)*

sure is low. When anatomy is normal, each atrium is connected to its ventricle through an atrioventricular (AV) valve, which opens and closes (see discussion later in this chapter). The valve on the left side is called the *mitral valve* and the one on the right side, the *tricuspid valve.* The right ventricle is banana shaped and pumps blood into the *pulmonary artery* through a tri-leaflet *pulmonic valve.* The left ventricle pumps blood into the *aorta* through a tri-leaflet *aortic valve.* The ventricles, especially the left ventricle, is thicker and less compliant in keeping with its need to generate higher pressures than the right ventricle, and intercavitary pressures are much higher than in the atria. Under normal conditions, the conduction or electrical system of the heart coordinates the sequential contraction of first the atria and then the ventri-

cles. Given they are connected, each side can effect the other. Under normal circumstances, the sequence of activation optimizes this interaction and thus the efficiency of cardiac function. The right and left coronary arteries originate from two of the three cusps of the aortic valve. They provide blood flow and thus nutritive perfusion to the heart. The largest vessels are on the epicardium and these can be accessed therapeutically fairly easily. Subsequent smaller branches divide to supply the remaining myocardium. The endocardium is the layer most susceptible to ischemia because its perfusion relies on the smallest vessels. There wall stress is greatest and opposition to flow occurs.

The myocardium contains bundles of striated muscle fibers, each of which is typically 10 to 15 μm in diameter and 30 to 60 μm in length. Work of the heart is generated by the alternating of the contraction and relaxation of these fibers. The fibers are composed of cardiac-specific contractile proteins actin and myosin, and regulatory proteins called troponins. They also contain a variety of enzymes that are vital for energy use, such as myoglobin, creatine kinase (CK), and lactate dehydrogenase (LD), some of which can be used as markers of cardiac injury.

PHYSIOLOGY

A typical cardiac cycle and the electrophysiology of the heart are discussed in this section.

Cardiac Cycle

A typical cardiac cycle consists of two intervals known as *systole* and *diastole* (Figure 44-2). During diastole, oxygenated blood returns from the lungs to the left atrium via the pulmonary veins and deoxygenated blood returns from other parts of the body to fill the right atrium. During this period, the AV valves are open, allowing passive filling of the ventricle. At the end of diastole, the atria contract, forcing additional blood through the AV valves and into the respective ventricles. During systole, the ventricles contract. This closes the AV valves when ventricular pressure exceeds atrial pressure and the pulmonary and aortic valves are opened when ventricular pressure exceeds the pressure in the pulmonary arteries and/or the aorta and blood flows into those conduits. During systole, a normal blood pressure in the aorta is typically 120 mm Hg, while during diastole, it falls to about 70 mm Hg. At rest, the heart pumps between 60 and 80 times per minute. Stroke volume (the amount of blood expelled with each contraction) is roughly 50 mL so cardiac output per minute is roughly 3 liters. Typically, we use values corrected for body surface area, which are usually in the range of 2.5 to 3.6 L/min/m^2. Measurements of cardiac output and ventricular filling pressures are the standards for assessing cardiac performance and function. Furthermore, therapeutic interventions in patients with heart disease are often assessed by determining cardiac output and ventricular pressures.[139]

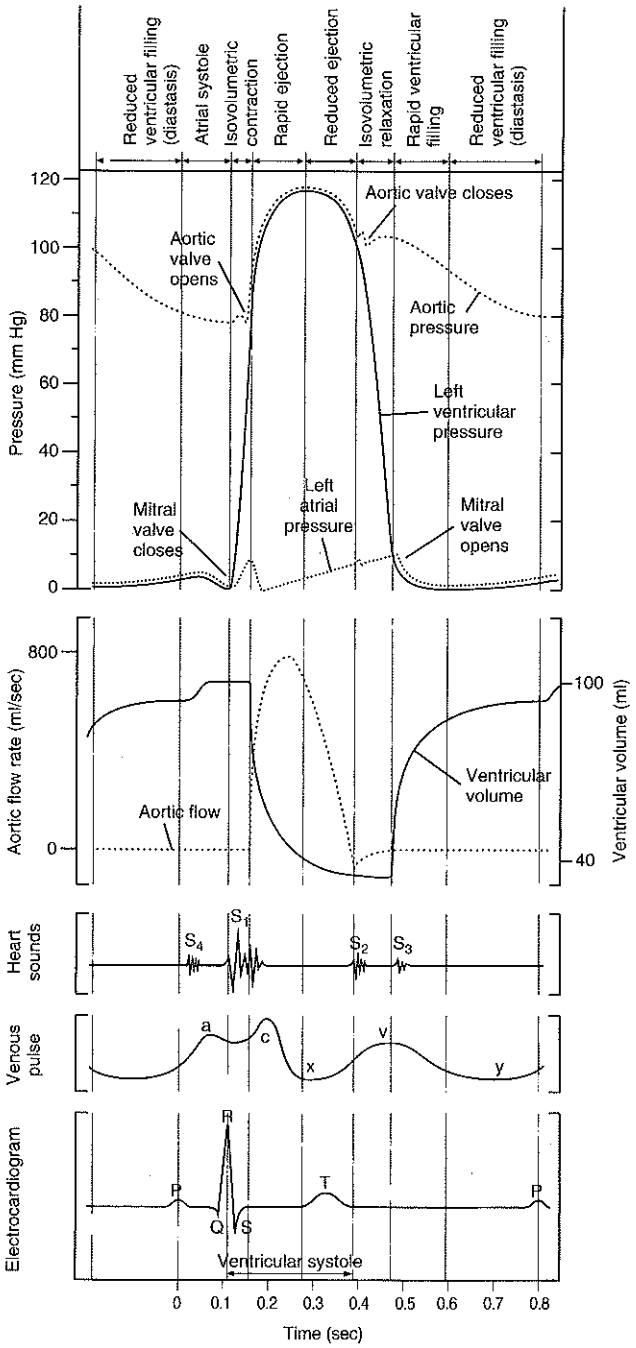

Figure 44-2 The cardiac cycle. *(From Dorland's Illustrated Medical Dictionary, 30th ed. Philadelphia: WB Saunders Co, 2003, with permission from the National Kidney Foundation.)*

Cardiac Conducting System

The cardiac cycle is tightly controlled by the cardiac conducting system, which initiates electrical impulses and carries them, via a specialized conducting system, to the myocardium. The surface electrocardiogram (ECG) records changes in potential and is a graphic tracing of the variations in electrical potential caused by the excitation of the heart muscle and detected at the body surface.[156] Clinically, the ECG is used to identify (1) anatomic, (2) metabolic, (3)

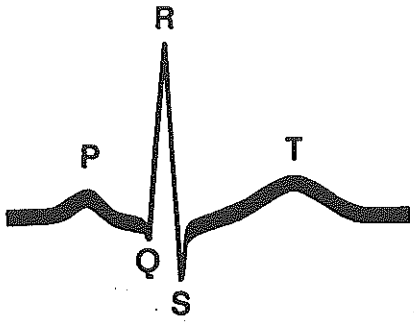

Figure 44-3 Electrocardiogram, serial tracing of a normal single heartbeat. Each beat manifests as five major waves: P, Q, R, S, and T. The QRS complex represents the ventricular contraction.

ionic, and (4) hemodynamic changes in the heart. The clinical sensitivity and specificity of ECG abnormalities are influenced by a wide spectrum of physiological and anatomical changes and the clinical situation.

Under normal circumstances, each electrical complex is similar and includes three major components (Figure 44-3): the atrial depolarization (the P wave), ventricular depolarization (the QRS complex), and repolarization (the ST segment and T wave). Atrial depolarization, which is manifested by the P wave, produces atrial contraction. Ventricular depolarization marked by the QRS complex produces contraction of the ventricles. It is composed of as many as three deflections: the Q wave, which when present is the first negative deflection; the R wave, which is the first positive deflection; and the S wave, which is a negative deflection following the R wave. On occasion, there is an R prime, which is a second positive deflection. Whether each of these occurs and their significance depends on the path of depolarization of the ventricles. Thus not every QRS complex will have discrete Q, R, and S waves. The ST segment and T wave are produced by the electrical recovery of the ventricles and their mean electrical vector is under normal circumstances concordant (i.e., in roughly the same direction) with the mean QRS vector.

A routine ECG is composed of 12 leads. Six are called limb leads (I, II, III, aVR, aVL, and aVF), because they are recorded between arm and leg electrodes, and six are called precordial or chest leads (V_1, V_2, V_3, V_4, V_5, and V_6) and are recorded across the sternum and left precordium. Each lead records the same electrical impulse but in a different position relative to the heart. Areas of pathology shown on the ECG can be localized by analyzing differences between the tracing in question and what is known to be normal in the 12 different leads.

CARDIAC DISEASE

There are many forms of cardiac disease. This chapter briefly covers congestive heart failure (CHF) and acute coronary syndromes, such as AMI. The vast number of other cardiac diseases are not discussed in depth here, because of the relatively minor role of diagnostic clinical laboratory tests in these disorders. However, the use of newer markers, such as the natriuretic peptides and the cardiac troponins, is changing that situation and is beginning to be of diagnostic utility in a number of disease states (see discussion later in this chapter).

CONGESTIVE HEART FAILURE

CHF is a condition in which there is ineffective pumping of the heart leading to an accumulation of fluid in the lungs. Typically, it results from a loss of cardiac tissue and subsequent function.[57] Medically, it is defined as the pathophysiological condition in which an abnormality of cardiac function is responsible for the failure of the heart to pump sufficient blood to satisfy the requirements of the metabolizing tissues. Encompassed in this definition are a wide spectrum of clinical conditions, ranging from (1) a primary impairment in pump function, such as might occur after a large AMI; (2) increased cardiac stiffness, which causes increases in pressure in the heart, restricts filling, and increases hydrostatic pressures behind the area of reduced compliance; and (3) situations in which peripheral demand is excessive, resulting in what is known as high output heart failure, which is defined as the inability of the heart to increase sufficiently to meet the peripheral demands for blood.

Epidemiology

In the United States, CHF is the only cardiovascular disease with an increasing incidence. The National Heart, Lung, Blood Institute estimates that current prevalence is 4.9 million Americans with CHF, with an incidence of approximately 400,000 new cases each year.[97,111] CHF is the leading cause of hospitalization in individuals 65 years and older. Current prognosis is dependent on disease severity, but overall it is poor. Five-year mortality is approximately 10% in mild CHF, 20% to 30% in moderate CHF, and up to 80% in end-stage disease.[121] These poor outcomes are not without substantial cost, estimated at $18.8 billion per year in the U.S.[95]

Currently, staging of CHF patients is with the New York Heart Association (NYHA) functional classifications I to IV. Class I patients are generally considered asymptomatic, with no restrictions on physical activity; class IV patients are often symptomatic at rest, with severe limitations on physical activity. The problem with this classification system is that much of it is based on subjective criteria. Thus patients with co-morbidities that reduce their activities are often not detected. In addition, there are many causes for dyspnea, which is the primary symptom in many of these individuals. Finally, many patients with ventricular dysfunction modify their activities to accomplish activities of daily living and thus lack overt symptoms until late in their disease. Thus patients with CHF often go undiagnosed and untreated early in their disease or are misdiagnosed because of diseases such as pulmonary disease. Initiating treatment in the more

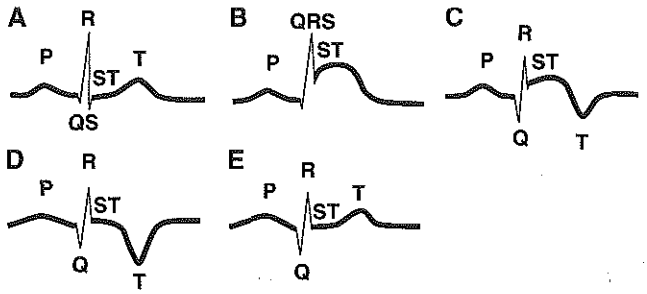

Figure 44-4 Electrocardiogram, serial tracing of a patient with an acute myocardial infarction. The sequence is **(A)** normal, **(B)** hours after infarction, the ST segment becomes elevated, **(C)** hours to days later, the T wave inverts and the Q wave becomes larger, **(D)** days to weeks later, the ST segment returns to near normal, and **(E)** weeks to months later, the T wave becomes upright again, but the large Q wave may remain.

advanced disease state is challenging (higher degree of irreversible cardiac function and patient deconditioning), more expensive (often requiring extended inpatient stay), and leaves patients with considerable morbidity on a daily basis. Obviously, misdiagnoses often lead to patient morbidity.

Clinical Manifestations

The clinical manifestations of heart failure vary considerably and depend on many factors, including the (1) clinical characteristics of the patient, (2) extent and rate at which the heart's performance becomes abnormal, (3) etiology of the heart disease, (4) concomitant co-morbidities, and (5) distribution of the abnormal cardiac function. The severity of impairment can range from mild—manifested clinically only during stress—to advanced, in which cardiac pump function is unable to sustain life without external support.

Acute Coronary Syndromes

The term acute coronary syndrome (ACS) encompasses patients who present with unstable ischemic heart disease.[40] If they have STE, they are called STE AMI (Figure 44-4). Usually, but not always, these individuals will develop Q waves on their ECGs, hence the term Q-wave MI. If they do not have STE but have biochemical criteria for cardiac injury, they are called NSTEMI and most do not develop ECG Q waves. Those who have unstable ischemia and do not manifest necrosis are designated patients with unstable angina (UA). Most of these syndromes occur in response to an acute event in the coronary artery when circulation to a region of the heart is obstructed. If the obstruction is high grade and persists, then necrosis usually ensues. Since necrosis is known to take some time to develop, it is apparent that opening the blocked coronary artery in a timely fashion can often prevent some of the death of myocardial tissue.[197] These syndromes are usually but not always associated with chest discomfort (see discussion later in this chapter).

The major cause of ACS is atherosclerosis, which contributes to significant narrowing of the artery lumen and a tendency for plaque disruption and thrombus formation.[40,164,165] Myocardial ischemia and infarction are usually segmental diseases. In up to 90% of patients with these diseases, there is a focal occlusion of only one of the three large coronary vessels or branches. The resulting impaired contractile performance of that segment occurs within seconds and is initially restricted to the affected segment(s). Myocardial ischemia and subsequent infarction usually begin in the endocardium and spread toward the epicardium.[186] The extent of myocardial injury reflects: (1) extent of the occlusion, (2) needs of the area deprived of perfusion, and (3) duration of the imbalance between coronary supply and thus substrate availability and the metabolic needs of the tissue. Irreversible cardiac injury consistently occurs in animals when the occlusion is complete for at least 15 to 20 minutes. Irreversible injury occurs maximally in the area "at risk" as supplied by the affected coronary artery. Most of the damage occurs within the first 2 to 3 hours.[186] Restoration of flow within the first 60 to 90 minutes evokes maximal salvage of tissue, but benefits are sufficient up to 4 to 6 hours to be associated with increased survival. In some situations, the restoration of coronary perfusion even later is of benefit.[197] The percentage of tissue at risk that undergoes necrosis (infarct size) depends on the amount of antegrade flow, the existing collateral flow, which is highly variable and difficult to predict, and the metabolic needs of the tissue.

In almost all instances, the left ventricle is affected by AMI. However, with right coronary and/or circumflex occlusions, the right ventricle can also be involved and there is a clinical syndrome in which the damage to the right ventricle predominates and is the major determinant of hemodynamics. Coronary thrombi will undergo spontaneous lysis, even if untreated, in about 50% of cases within 10 days. However, for patients with STE AMI, opening the vessel earlier with clot dissolving agents (thrombolysis) and/or percutaneous intervention can often save myocardium and lives (Figure 44-5).[197] Consequently, percutaneous intervention (PCI) with stenting is the preferred therapy for STE AMI. However, many hospitals cannot or do not offer urgent PCI 24 hours a day, 365 days per year. Thus clot-dissolving medications still play a major role in the treatment of these patients. In addition, it is now apparent that urgent invasive revascularization also benefits those with NSTEMI.[40] These individuals usually have only partial coronary occlusion and smaller amounts of cardiac damage acutely. However, untreated, there are often repetitive episodes that eventually damage larger amounts of myocardium, leading to increased morbidity and mortality over time. We now know that many treatments, such as newer anticoagulant, antiplatelet, and antiinflammatory agents in conjunction with coronary revascularization, save lives in this group.

The prognosis for patients with ischemia but without necrosis is far better, and there are no differences thus far described that distinguish medical from invasive therapies.

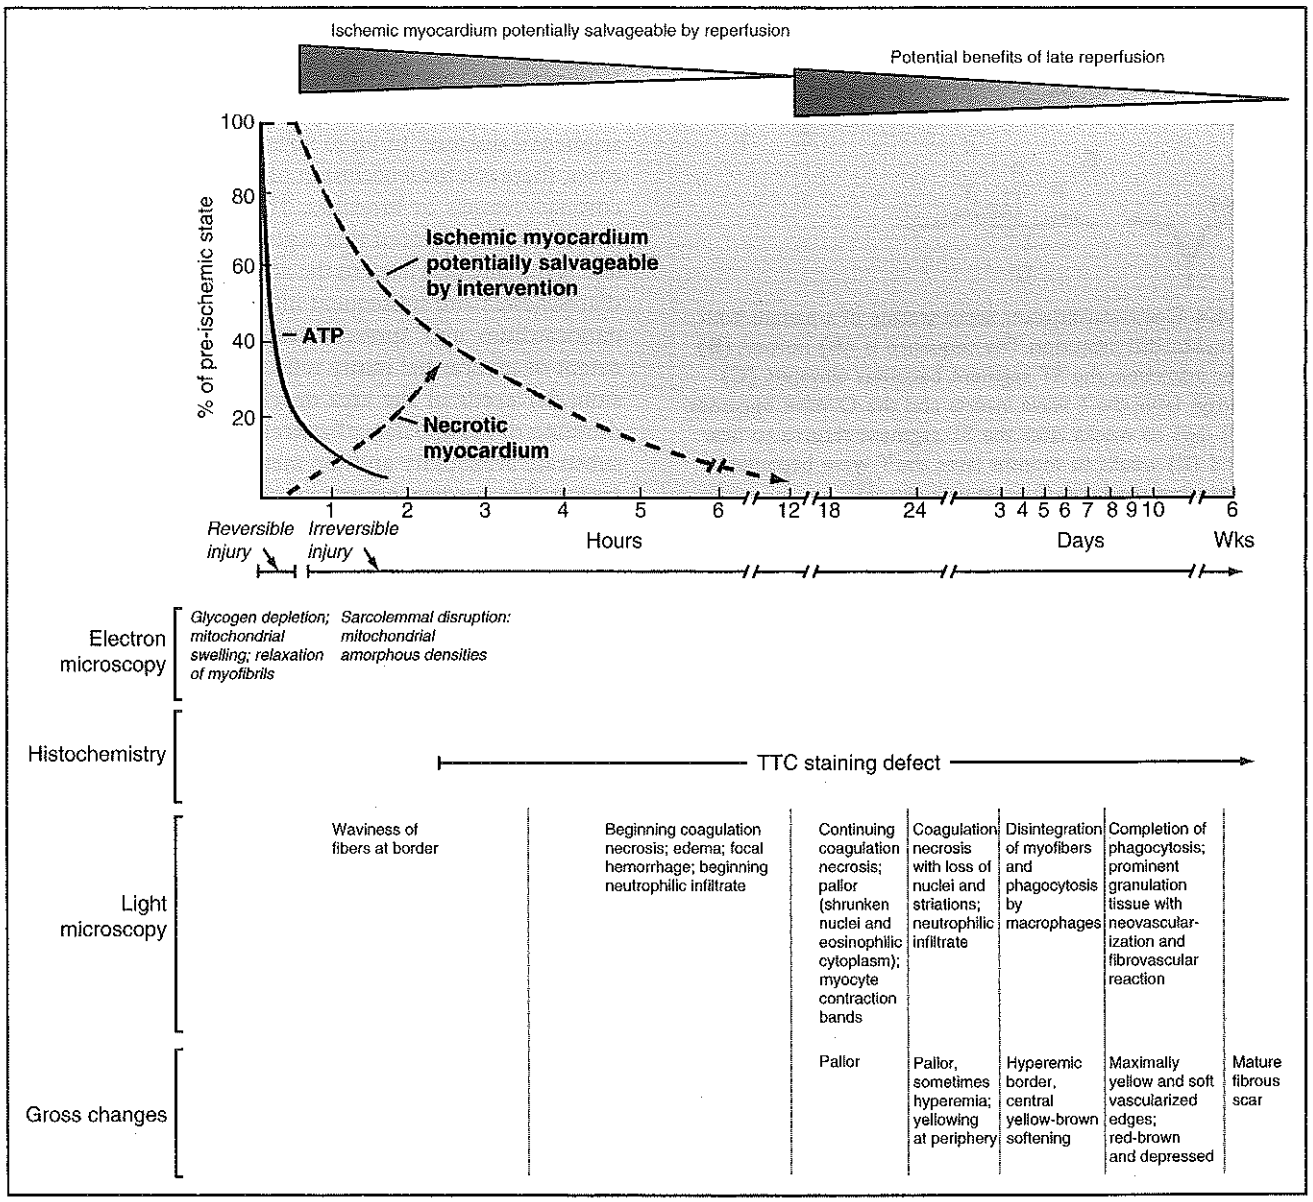

Figure 44-5 Temporal sequence of myocardial infarction. *(From Antman EM, Braunwald E. Acute myocardial infarction. In: Braunwald E, ed. Heart disease: a textbook of cardiovascular medicine, 5th ed. Philadelphia: WB Saunders Co, 1997:1189.)*

A major determinant of mortality and morbidity is the amount of myocardial damage. With STE AMI, most of it is acute whereas with NSTEMI, it may evolve because of repetitive events over many months, thus interrupting the process improves survival.

Precipitating Factors

In many patients with AMI, no precipitating factor can be identified. Studies have noted the following patient activities at the onset of AMI: (1) heavy physical exertion, 13%; (2) modest or usual exertion, 18%; (3) surgical procedure, 6%; (4) rest, 51%; and (5) sleep, 8%. If and when these activities are the trigger for infarction, the window of risk is often brief, usually only an hour or two. The severe exertion that preceded an infarction was often performed at times when the patient was fatigued or emotionally stressed. Exertion before infarction is somewhat more common among patients without preexisting angina than in patients who have had a history of angina.[200]

There are causes of infarctions other than acute atherothrombotic coronary occlusion. For example, prolonged vasospasm can induce infarction, and spontaneous dissection is becoming more commonly appreciated, especially in pregnant females.[40] Other conditions (Box 44-1) can also cause the death of cardiomyocytes and lead to a biochemical signal of myocyte damage, but these entities should not be confused with myocardial infarction.[102] Some of these injurious stimuli include (1) trauma that may precip-

itate myocardial contusion and hemorrhage into the myocardium; (2) toxic reactions to chemotherapy agents, such as Adriamycin, or myocardial depressant substances released with sepsis; (3) heat-induced injury after cardioversion; (4) increases in wall stress with impairment of subendocardial perfusion caused by severe hypotension or hypertension; and/or (5) injury caused by catecholamine release in patients with acute neurological catastrophes. Pulmonary embolism is another common cause of biochemical elevations and is caused by right ventricular damage related to the acute increases in wall stress and reduced subendocardial perfusion.[79,123,126]

Chronobiology

There is a pronounced periodicity for the time of onset of STE AMI.[200] Often an AMI occurs in the morning hours soon after arising, a period of (1) increasing adrenergic activity, (2) increased plasma fibrinogen levels, (3) increased inhibition of fibrinolysis, and (4) increased platelet adhesiveness. Studies have demonstrated that the early morning peak in MI parallels the peak incidence of death from ischemic heart disease, occurring at about 8 AM to 9 AM There also is a second peak at approximately 5 PM. Circadian rhythms affect many physiological and biochemical parameters; the early morning hours are associated with rises in plasma catecholamines and cortisol and increases in platelet aggregability. Tissue plasminogen activator activity is low and plasminogen activator inhibitor activity is high during the early morning hours. Thus it is possible that some cyclical aspects of combined vasospastic, prothrombotic, and fibrinolytic factors, in the setting of preexisting atherosclerosis, lead to AMI.[20] NSTEMI does not exhibit this circadian rhythm.

Prognosis

STE and non-STE infarctions have distinctly different short-term prognoses. STE AMI is associated with a higher early and in-hospital mortality. It is said that mortality associated by STE AMI can occur up to 6 months post event, but the vast majority (at least two thirds) occurs during the first 30 or 40 days. It is this process that coronary recanalization seems to benefit.[5] NSTE AMI is associated with a lower acute mortality and complication rates but a longer period of vulnerability to reinfarction and death. As a result, 1- to 2-year survival rates are similar to those for transmural infarction.[40] This is why intervention has been so effective in this group.

Clinical History

The clinical history remains of substantial value in establishing a diagnosis.[40,98,197] A prodromal history of angina can be elicited in 40% to 50% of patients with AMI. Of the patients with AMI presenting with prodromal symptoms, approximately one third have had symptoms from 1 to 4 weeks before hospitalization; in the remaining two thirds, symptoms predate admission by a week or less, with one third of these patients having had symptoms for 24 hours or less.

The pain of AMI is variable in intensity; in most patients it is severe but rarely intolerable. The pain may be prolonged, up to 30 minutes. The discomfort is described as constricting, crushing, oppressing, or compressing; often the patient complains of something sitting on or squeezing the chest. Although usually described as a squeezing, choking, viselike, or heavy pain, it may also be characterized as a stabbing, knifelike, boring, or burning discomfort. The pain is usually retrosternal in location, spreading frequently to both sides of the chest, favoring the left side. Often the pain radiates down the left arm. Some patients note only a dull ache or numbness of the wrists in association with severe substernal discomfort. In some instances, the pain of AMI may begin in the epigastrium and simulate a variety of abdominal disorders, which often causes MI to be misdiagnosed as indigestion. In other patients, the discomfort of AMI radiates to the shoulders, upper extremities, neck, and jaw, again usually favoring the left side. In patients with preexisting angina, the pain of infarction usually resembles that of angina with respect to features and location. However, it is generally much more severe, lasts longer, and/or is not relieved by rest and nitroglycerin.

Older individuals, diabetics, and women often present atypically.[40,98,197] For example, in individuals older than 80 years, less than 50% of those who present with AMI will have chest discomfort. Sometimes, these patients will present with shortness of breath, fatigue, or even confusion. The pain of AMI may have disappeared by the time physicians first encounter the patient (or the patient reaches the hospital), or it may persist for a few hours.

Myocardial Changes Following Acute Myocardial Infarction

Figure 44-5 shows the temporal sequence of early biochemical, histochemical, and histological findings after the onset of AMI. On gross pathological examination, AMI can be divided into subendocardial (nontransmural) infarctions and transmural infarctions.[10] In the former, necrosis involves the endocardium, the intramural myocardium, or both without extending all the way through the ventricular wall to the epicardium. In the latter, myocardial necrosis involves the full thickness of the ventricular wall. The histological pattern of necrosis may differ: contraction band injury occurs almost twice as often in nontransmural infarctions as in transmural infarctions. Unfortunately, the pathological changes correlate poorly with clinical, ECG, and biochemical markers of necrosis, which is why those terms are no longer used clinically. It is fair to say, however, that on a statistical basis, one is more apt to have STE MI Q waves on the ECG and a larger biochemical signal when the infarction is transmural pathologically.

Ultrastructural (Electron Microscopic) Changes in Myocardium

In experimental infarction, the earliest ultrastructural changes in cardiac muscle following occlusion of a coronary artery, noted within 20 minutes by electron microscopy, consist of a reduction in the size and number of glycogen granules, intracellular edema, and swelling and distortion of the transverse tubular system, the sarcoplasmic reticulum, and the mitochondria. These early changes are partially reversible. Changes after 60 minutes of occlusion include myocardial cell swelling; mitochondrial abnormalities, such as swelling and internal disruption; development of amorphous, flocculent aggregation and margination of nuclear chromatin; and relaxation of myofibrils. After 20 minutes to 2 hours of ischemia, changes in some cells become irreversible, and there is progression of these alterations; additional changes include swollen sacs of the sarcoplasmic reticulum at the level of the A band, greatly enlarged mitochondria with few cristae, thinning and fractionation of myofilaments, disorientation of myofibrils, and clumping of mitochondria. Cells irreversibly damaged by ischemia are usually swollen, with an enlarged sarcoplasmic reticulum. Defects in the plasma membrane may appear, and the mitochondria are fragmented. Many of these changes become more intense when blood flow is restored.

Histological (Light Microscopic) Changes in Myocardium

Although it was previously believed that no light microscopic changes could be seen in infarcted myocardium until 8 hours after interruption of blood flow, in some infarcts a pattern of wavy myocardial fibers may be seen 1 to 3 hours after onset, especially at the periphery of the infarct.[10] After 8 hours, edema of the interstitium becomes evident, as do increased fatty deposits in the muscle fibers, along with infiltration of neutrophilic polymorphonuclear leukocytes and red blood cells.

By 24 hours there is clumping of the cytoplasm and loss of crossstriations, with appearance of irregular crossbands in the involved myocardial fibers. The nuclei sometimes even disappear. The myocardial capillaries in the involved region dilate, and polymorphonuclear leukocytes accumulate, first at the periphery and then in the center of the infarct. During the first 3 days, the interstitial tissue becomes edematous. Generally, on about day 4 after infarction, removal of necrotic fibers by macrophages begins, again commencing at the periphery. By day 8, the necrotic muscle fibers have become dissolved; by about 10 days, the number of polymorphonuclear leukocytes is reduced, and granulation tissue first appears at the periphery. Removal of necrotic muscle cells continues until the fourth to sixth week following infarction, by which time much of the necrotic myocardium has been removed. This process continues, along with increasing collagenization of the infarcted area. By the sixth week, the infarcted area has usually been converted into a firm connective tissue scar with interspersed intact muscle fibers.

Gross Changes in Myocardium

Gross alterations of the myocardium are difficult to identify until at least 6 to 12 hours following the onset of necrosis.[10] However, several histochemical approaches have been used to identify zones of necrosis that can be observed after only 2 to 3 hours. Initially, the myocardium in the affected region may appear pale and slightly swollen. By 18 to 36 hours after onset of the infarct, the myocardium is tan or reddish purple (because of trapped erythrocytes). These changes persist for approximately 48 hours; the infarct then turns gray and fine yellow lines, secondary to neutrophilic infiltration, appear at its periphery. This zone gradually widens and during the next few days extends throughout the infarct.

Eight to 10 days following infarction, the thickness of the cardiac wall in the area of the infarct is reduced as necrotic muscle is removed by mononuclear cells. The cut surface of an infarct of this age is yellow, surrounded by a reddish purple band of granulation tissue that extends through the necrotic tissue by 3 to 4 weeks. Over the next 2 to 3 months, the infarcted area gradually acquires a gelatinous, gray appearance, eventually converting into a shrunken, thin, firm scar that whitens and firms progressively with time. This process begins at the periphery of the infarct and gradually moves centrally. In addition, more hemorrhage is seen

in the area of damage because of the use of potent thrombolytic and anticoagulant agents.

The Development and Progression of Atherosclerosis[133]

Intrinsic to the modern day understanding of ischemic heart disease and particularly why there is such intense interest in the development of markers of inflammation is the concept that atherosclerosis is a chronic inflammatory disease (see Chapter 26). The concept is that some event damages the endothelium of blood vessels, which facilitates the egress of lipid into the subendothelial space. Putative injurious stimuli include turbulent flow in a blood vessel, which could occur for example because of hypertension or a noxious metabolite from a lipid fraction. This damage tends to occur at branch points of blood vessels. Regardless of the initial stimulus, once damaged, low density lipoprotein (LDL) can cross into the vessel wall more easily in an NADPH oxidase mediated fashion. Whether minimal oxidation facilitates that egress or whether it occurs once the LDL is within the vessel wall is unclear, but a minimal degree of oxidation once in the vessel wall facilitates the egress of smooth muscle cells from the media of the vessel and macrophages that ingest cholesterol. Hence the current enthusiasm for the measurement of oxidized lipids. The process of atherosclerosis then progresses slowly with the involvement of lymphocytes, monocytes, macrophages, and smooth muscle cells. The dynamic within a given plaque may vary, but there clearly is an inflammatory milieu, in part mediated by substances like CD40 ligand, which can be measured in patients either directly or as one of the stimuli to the elaboration of C-reactive protein (CRP). Interleukins 1, 6, 8, and 18 also participate to various extents as part of this process chronically (see Chapter 22). This process also involves adherence of white blood cells to the damaged endothelial surface with subsequent degranulation and elaboration of myeloperoxidase. There also is a procoagulant component due predominantly to the presence of tissue factor, which is localized immediately under the cap of the plaque. There also is intermittent instability because of inflammatory products within the plaque that release chemicals that degrade ground substance, such as metalloproteinases. Initially the plaque expands by stretching the adventitia in a process of small ruptures with release of procoagulant and proinflammatory materials and then remodeling over time as antiinflammatory and anticoagulant and thrombolytic substances are elaborated. This process of stretching the adventitia preserves the lumen such that by the time luminal encroachment occurs, there is a very large plaque burden.[83]

A categorization of plaques has been proposed to facilitate identification of those at risk of rupture that could lead to an acute event. It is acknowledged that the propensity for a plaque to rupture probably reflects a systemic predilection rather than a local one. Thus for a given patient at risk, there likely are many plaques that are metabolically at risk of rupture at any given instance.[164,165] High risk plaques have:

1. An active inflammatory environment that may not only be intrinsic but may be stimulated additionally by systemic infections.
2. A thin fibrous cap on the endothelial surface with a large lipid core that is filled with procoagulant substances, predominantly tissue factor.
3. Endothelial denudation and fissuring because of the elaboration of metalloproteinases.
4. Local high shear stress usually because they are severe and at branch points in the vessel.

Events likely occur because of superimposed thrombosis. This can be caused by erosions on the surface of the plaque or more often because of rupture of the plaque at its edges, where the cap is thinnest and the majority of the metalloproteinases reside. If rupture induces total thrombotic occlusion, the event is usually an STE AMI. If lesser degrees of occlusion occur, an NSTE AMI or UA may ensue. One of the causes that may participate in subtotal occlusive plaque rupture involves platelets and abnormal coronary vasomotion. It is known that diseased coronary arteries respond atypically to many stimuli, often constricting rather than dilating. Since the cross sectional area of a vessel is related to the square of the radius, even modest amounts of constriction can markedly increase the extent of occlusion. Whether constriction occurs first, leading to stagnation of coronary flow and platelet aggregation on the plaque, or whether platelets stick and cause the aggregation is not certain, but these processes reinforce one another. Platelets secrete vasoconstricting substances in response to a denuded area, which expresses adhesive receptors (e.g., CAMs). This, in addition to stagnant blood flow, will cause platelets and white blood cells to adhere to the surface of the vessels. It appears likely that in many patients that platelets adhere and enhance vasoconstriction and then break off, causing small vessel emboli, sometimes in association with plaque debris and sometimes without. These processes, in addition to a reduction in flow, can lead to necrosis or at least recurrent ischemia. It is also apparent that the process that eventually leads to acute events involves a systemic propensity to platelet aggregation and inflammation since effluent flowing from the nonculprit vessel (distant from the putative coronary lesion causing the acute event) elaborates inflammatory mediators (e.g., myeloperoxidase) similar to those observed from the affected vessel. Finally, necrosis when present also stimulates acute phase reaction, including an inflammatory component.

Given this pathophysiology, many therapies are now oriented toward inhibition of thrombosis, fibrinolysis, platelet aggregation, and inflammation. Some of the same ways of assessing their efficacy are the ones used diagnostically.

Diagnosis of Acute Myocardial Infarction

Previously, the diagnosis of AMI established by the World Health Organization required at least two of the following criteria: (1) a history of chest pain, (2) evolutionary changes

BOX 44-2 Diagnosis of Acute Myocardial Infarction

Either one of the following criteria satisfies the diagnosis for an acute, evolving, or recent MI.

1. Typical rise and gradual fall (cardiac troponin) or more rapid rise and fall (CK-MB) of biochemical markers of myocardial necrosis with at least one of the following:
   a. Ischemic symptoms
   b. Development of pathological Q waves on the ECG
   c. ECG changes indicative of ischemia (ST segment elevation or depression)
   d. Coronary artery intervention (e.g., coronary angioplasty)
2. Pathological findings of an AMI

BOX 44-3 Diagnosis of Established Myocardial Infarction

1. Any one of the following criteria satisfies the diagnosis for established MI.
   a. Development of new pathologic Q waves on serial ECGs. The patient may or may not remember previous symptoms. Biochemical markers of myocardial necrosis may have normalized, depending on the length of time that has passed since the infarct developed.
   b. Pathological findings of a healed or healing MI.

on the ECG, and/or (3) elevations of serial cardiac markers. However, it was rare for a diagnosis of AMI to be made in the absence of biochemical evidence of myocardial injury. A 2000 ESC/ACC consensus conference has codified the role of markers by advocating that the diagnosis be evidence of myocardial injury based on markers of cardiac damage in the appropriate clinical situation (Box 44-2).[6] The criteria for diagnosis of an established MI are in Box 44-3. The guidelines thus recognized the reality that neither the clinical presentation nor the ECG had adequate sensitivity and specificity. This guideline does not suggest that all elevations of these biomarkers should elicit a diagnosis of AMI—only those associated with the appropriate clinical and ECG findings (see discussion later in this chapter). When elevations that are not caused by acute ischemia occur, the clinician is obligated to search for another etiology for the elevation.[21,59] The criteria suggested for use with these markers by the Biochemistry Panel of the ESC/ACC Committee are listed in Box 44-4.[103]

ECG Findings[104]

The initial ECG used to be diagnostic of AMI in about 50% of AMI patients. As the frequency of STE AMI has diminished and the diagnosis has been made with greater and greater sensitivity, this percentage has been greatly reduced. Serial tracings are helpful for STE AMI but not for what is now almost 70% of AMIs, those with NSTE AMI. The classic

BOX 44-4 ESC/ACC Recommendations for Use of Cardiac Biomarkers for Detection of Myocardial Injury and Myocardial Infarction

- Increases in biomarkers of cardiac injury are indicative of injury to the myocardium, but not an ischemic mechanism of injury
- Cardiac troponins (I or T) are preferred markers for diagnosis of myocardial injury
- Increases in cardiac marker proteins reflect irreversible injury
- Improved quality control of troponin assays is essential
- MI is present when there is cardiac damage, as detected by marker proteins (an increase above the 99th percentile of the normal range) in a clinical setting consistent with myocardial ischemia.
- For patients with an ischemic mechanism of injury, prognosis is related to the extent of troponin increases.
- If an ischemic mechanism is unlikely, other etiologies for cardiac injury should be pursued.
- Samples must be obtained at least 6 to 9 hr after the symptoms begin.
- After PCI and CABG, the significance of marker elevations and patient care should be individualized.

PCI, Percutaneous coronary intervention; *CABG,* coronary artery bypass gnaft.

ECG changes of an STE AMI are ST segment elevation, which often evolve to the development of Q waves absent intervention (see Figure 44-4). Pericarditis, some normal variants, and transient causes that may not result in myocardial injury are well described and can on occasion mimic the changes of AMI. Most NSTE AMIs present with either ST segment depression, with or without T-wave changes; T-wave changes alone; or on occasion in the absent of any ECG findings. Those with ST segment change have a substantially worse prognosis.

In some patients, the clinical history and ECG may be definitive. In others, it may not be as clear. There are many other clinical aspects that might suggest AMI as the etiology of a given biomarker elevation. For example, the finding of significant coronary obstructive lesions, especially in a pattern suggestive of recent plaque rupture, is highly suggestive.[103] At times, a positive stress test with or without imaging may be what helps make the diagnosis. However, if the clinical situation is not suggestive, other sources for cardiac injury should be sought.

Cardiac Markers

A cardiac marker is defined as a clinical laboratory test useful for detecting AMI or minor myocardial injury. They are most useful when patients have nondiagnostic ECG tracings. Patients with AMI can be categorized into four groups. First, there is the group of patients who present early to the emergency department (ED), within 0 to 4 hours after the onset of chest pain, without diagnostic ECG evidence of AMI. For laboratory tests to be clinically useful, markers of MI must be released rapidly from the heart into the circulation to provide sensitive and specific diagnostic information.

Further the analytical assays must be rapid and sensitive enough to distinguish small changes within the reference interval in serum. The second group of patients are those presenting 4 to 48 hours after the onset of chest pain, without evidence of AMI on ECG. In this group of patients, the diagnosis of AMI requires serial monitoring of both cardiac markers and ECG changes. In the third group are patients who present more than 48 hours after the onset of chest pain with nonspecific ECG changes. The ideal marker of myocardial injury in this group would persist in the circulation for several days to provide a late diagnostic time window. The shortfall of such a marker might be its inability to distinguish recurrent injury from old injury. The fourth group of patients are those who present to the ED at any time after the onset of chest pain with clear ECG evidence of AMI. In this group, detection with serum markers of myocardial injury is not necessary. Since a subgroup of these patients may qualify for thrombolytic therapy, specific and sensitive myocardial markers could be employed to monitor the success of reperfusion during the 60- to 90-minute period after therapy. Rapid assays providing early serial values followed by interpretation of the markers' patterns of appearance may assist clinicians in providing alternative or intervention therapies when thrombolytics have not been successful.

CARDIAC BIOMARKERS

Numerous biomarkers have been monitored to assess myocardial injury. Most are myocardial proteins and differ in their (1) location within the myocyte, (2) release kinetics after damage, and (3) clearance from the circulation. A number of other molecules also are thought to have potential as biomarkers.

CARDIAC TROPONIN I AND T

The contractile proteins of the myofibril include the regulatory proteins troponin. The troponins are a complex of three protein subunits, troponin C (the calcium-binding component), troponin I (the inhibitory component), and troponin T (the tropomyosin-binding component).[117,146] The subunits exist in a number of isoforms. The distribution of these isoforms varies between cardiac muscle and slow and fast twitch skeletal muscle. Only two major isoforms of troponin C are found in human heart and skeletal muscle. These are characteristic of slow and fast twitch skeletal muscle. The heart isoform is identical with the slow twitch skeletal muscle isoform. Isoforms of cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI) also have been identified and are the products of unique genes.[37,60,114,129] Troponin is localized primarily in the myofibrils (94% to 97%), with a smaller cytoplasmic fraction (3% to 6%).

Cardiac troponin subunits I and T have different amino acid sequences encoded by different genes. Human cTnI has an additional post translational 31–amino acid residue on the amino terminal end compared with skeletal muscle TnI, giving it unique cardiac specificity. Only one isoform has been identified. cTnI has never been shown to be expressed in normal, regenerating, or diseased human or animal skeletal muscle.[38] Troponin T is also encoded by a different gene than encodes skeletal muscle isoforms. An 11–amino acid amino terminal residue gives this marker unique cardiac specificity. However, during human fetal development, in regenerating rat skeletal muscle, and in diseased human skeletal muscle, small amounts of cTnT are expressed as one of four identified isoforms in skeletal muscle.[9,39,199] In humans, cTnT isoform expression has been demonstrated in skeletal muscle specimens obtained from patients with muscular dystrophy, polymyositis, dermatomyositis, and end-stage renal disease.[39,153,187,199] Thus care is necessary to choose antibody pairs for cardiac assay use that do not detect the isoforms reexpressed in noncardiac tissue.

BOX 44-5 Tissue and Circulating Forms of Cardiac Troponin

1. Tissue and cytosolic
   a. TIC complex >95% myofibril
   b. TIC, IC, free I, free T <5% cytosol
2. Multiple modifications—tissue and blood
   a. C and N terminal degradation
   b. Phosphorylation
   c. Oxidation, reduction
3. Complex association/dissociation

Cardiac troponin I exists as a part of the troponin T-I-C ternary complex as a structural and regulatory component of the myofibril. A substantial body of evidence now exists that shows that following myocardial injury or because of genetic disposition, multiple forms are elaborated both in tissue and in blood. The multiple forms of cTnI are listed and described in Box 44-5.[229] These include the T-I-C ternary complex, IC binary complex, and free I. Multiple modifications of these three forms can exist, involving oxidation, reduction, phosphorylation and dephosphorylation, and both C and N terminal degradation. Figure 44-6 illustrates the detection of seven different cTnI forms in an injured human heart.[112] Figure 44-7 further demonstrates that different antibody configurations can lead to a substantially different recognition pattern depending on the selection of antibodies used to detect cTnI.[112] Figure 44-8 shows a schematic of the cTn molecule and what epitope locations are more prone to alterations and what regions are most stable.[54] The conclusions from these observations are that assays need to be developed in which the antibodies recognize epitopes in the stable region of cTnI and ideally, demonstrate an equimolar response to the different cTnI forms that do circulate in the blood.[176]

BRAIN NATRIURETIC PEPTIDE

Brain (or B-type) natriuretic peptide (BNP) is a hormone that was originally isolated from porcine brain tissue. It has

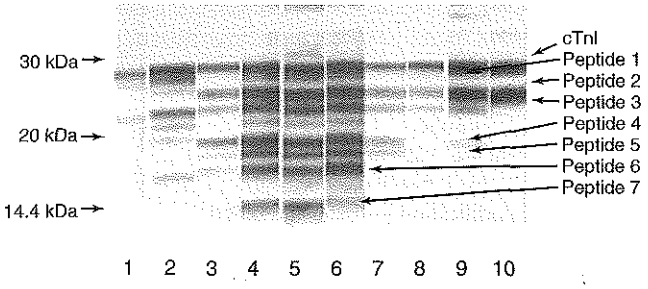

Figure 44-6 Western blot analysis of endogenous proteolytic fragments of cTnI antibodies. *(From Katrukha AG, Bereznikova AV, Filtaov VL, Esakova TV, Kolosova OV, Pettersson K, et al. Degradation of cardiac troponin I: implication for reliable immunodetection. Clin Chem 1998;44:2433-40.)*

Degradation of cardiac troponin I: implication for reliable immunodetection. Clin Chem 1998;44:2433-40.)*

biological effects similar to those of atrial natriuretic peptide (ANP) and is stored mainly in the myocardium of the cardiac ventricles. Blood levels of BNP are elevated in hypervolemic states, such as congestive heart failure and hypertension.

For the past decade, there has been increasing research of natriuretic peptides, specifically as a diagnostic marker for CHF.[173a] In November 2000, the FDA approved the first assay for detection of BNP on a point-of-care testing (POCT) platform (Biosite Triage). This effectively took BNP measurement out of the realm of research (predominant research assay, an RIA marketed by Shionogi) and provided access for monitoring BNP to the vast majority of healthcare. Since 2002, the FDA has approved the Bayer BNP, the Abbott AxSYM BNP, the Beckman Access BNP, and the Roche N-terminal proBNP (NT-proBNP) assays.

Natriuretic peptides (NP) are secreted to regulate fluid volume, blood pressure, and electrolyte balance. They have activity in both the central and peripheral nervous systems. ANP was the first described in 1981. BNP was discovered 7 years later in the porcine brain, thus the name.[232] However, in humans, while produced in the brain, the main source of circulatory BNP is the heart ventricles. Other members of the NP family include C-type natriuretic peptide (CNP) and urodilatin. Although these two hormones are not produced by myocardium, they are released with ANP and BNP in patients with volume overload, hypertension, and hyponatremia.

ANP and BNP are released in response to atrial and/or ventricular stretch from volume overload. Correspondingly,

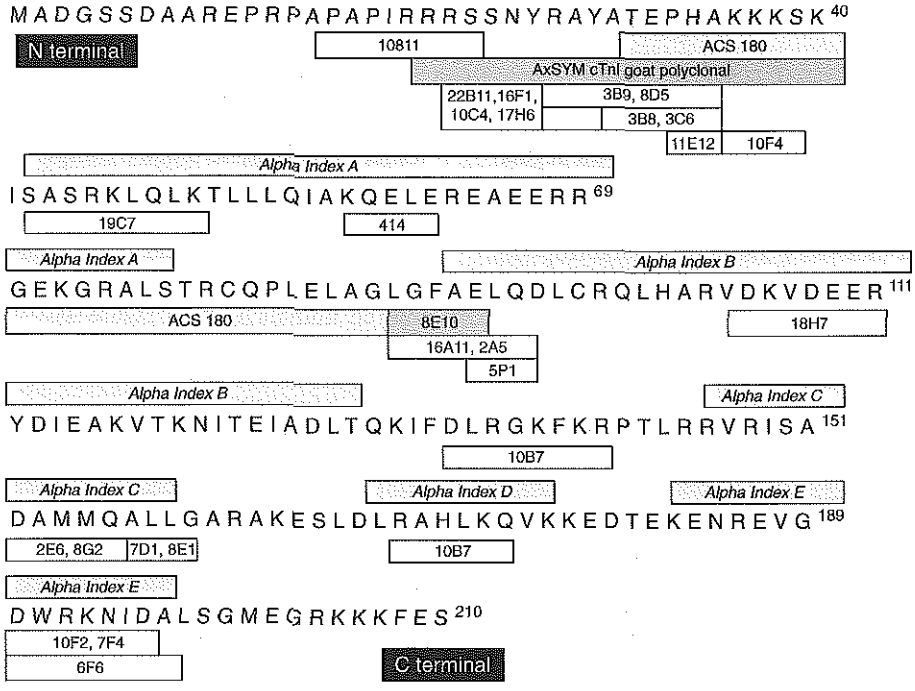

Figure 44-8 Amino acid sequence of cardiac troponin I, with identification of epitopes used by two manufacturers' cTnI assays. *(From Collinson PO, Boa FG, Gaze DC. Measurement of cardiac troponins. Ann Clin Biochem 2001;38:423-49. Figure courtesy Paul Collinson.)*

blood NPs increase in all diseases with volume overload, including renal and liver diseases, and some endocrine disorders (e.g., Cushing's disease, primary hyperaldosteronism). Thus increased NPs are not entirely specific for heart failure. NPs increase cardiac output by decreasing systemic and pulmonary vascular resistance. Additionally, the actions of NPs reduce production of renin and aldosterone by increasing renal blood flow, glomerular filtration rate (GFR), and urine output. Overall, NPs are one of the body's main tools in regulating blood pressure and volume status. They also have direct effects on the myocardial interstitium.

BNP synthesis mostly relies on gene expression and initial upregulation of mRNA.[122] Figure 44-9 illustrates the synthesis of the prepro-hormone and subsequent secretion of BNP from the cardiac myocytes. There is uncertainty whether proBNP is split in the myocyte or later in the plasma, but it is known that there is a circulating protease called corin that is capable of cleaving the NT terminal and the active BNP moiety.[210] Circulating proBNP has been documented. However, the major circulating forms are the resulting NT-proBNP, function unknown, and C-terminal BNP (physiologically active hormone). BNP is cleared via degradation by NEP (neutral endopeptidases), by receptor mediated clearance, and perhaps a bit via the kidneys, which also can secrete BNP. The NT-pro fragment is not cleared via receptor mediated mechanisms, but is thought to be predominantly cleared by the kidneys. Therefore, it will be more sensitive to changes in renal function. The majority of research on natriuretic peptides in CHF has focused on BNP and NT-proBNP.

BNP has a multiplicity of cardiac functions and is released as a counter-regulatory hormone in response to a variety of cardiac stresses but most particularly cardiac stretch. It is significantly affected by changes in volume and in cardiac performance, and among its effects are volume reduction and vasodilation. Thus this hormone is a sensitive marker for changes in ventricular physiology. BNP, like its close counterpart ANP, is released likely as a prohormone. Once in plasma, the leader sequence of 76 amino acids, known as NT-proBNP, is cleaved (see Figure 44-9) leaving the active 32–amino acid moiety to circulate.[132] Circulating concentrations of BNP are age and gender dependent.[185] In addition, they are increased in chronic heart failure and are correlated with its severity.[235] Early studies have demonstrated that BNP secretion reflects regional wall stress in the ventricles and is thus associated with adverse ventricular remodeling and poor prognosis after AMI.[173,190] It is now apparent that BNP measurements are useful in identifying patients with moderate to severe CHF, which can at times be reasonably occult,[148] and for risk stratification of CHF patients[34,100] and those who present with ACS.[64,100,159] The data suggest that this analyte provides information that is synergistic with the measurement of troponin in these settings and is especially useful for risk stratification when troponins are normal.[64,100,159] However, in contrast to troponin markers, there have yet to be differences in treatment that are known to influence prognosis when BNP is elevated. The clinical use of the enzyme-linked immunosorbent assays (ELISA), assays that measure both for the active entity and the NT-proBNP fragment will be discussed in more detail later in this chapter.

Creatine Kinase Isoenzymes and Isoforms

Three cytosolic isoenzymes (CK-3, CK-2, CK-1) and one mitochondrial isoenzyme (CK-Mt) of creatine kinase (CK) (MW 80,000 Da for all 4 isoenzymes) have been identified and are easily separated on agarose and cellulose acetate by electrophoresis (see Chapter 21).[128] Three different genes have been identified that encode for and are specific for CK-M, CK-B, and mitochondrial CK subunits.[181,196] Although CK-3 (CK-MM) is predominant in both heart and skeletal muscle, CK-2 (CK-MB) has been shown to be more specific for the myocardium, which contains 10% to 20% of its total CK activity as CK-MB, compared with amounts varying from 2% to 5% in skeletal muscle.

Numerous investigators have shown that electrophoresis of CK isoenzymes, using extended electrophoresis times or electrophoresis at higher voltages, further separates the bands of CK-MM and CK-MB.[48,224] At least three CK-MM isoforms and at least 4 CK-MB isoforms (subtypes of the individual isoenzymes) exist. The tissue isoform (gene product) of CK-MM is designated CK-MM_3. When this protein/enzyme is released into the circulation, a time-mediated carboxypeptidase hydrolysis of C-terminal lysine residues occurs, giving rise to at least two posttranslational products: CK-MM_2 and CK-MM_1.[180] Similarly, following release of the CK-MB tissue isoform into the circulation, carboxypeptidase cleavage of the CK-B carboxy-terminal lysine residue gives rise to a B-chain negative product and then a product devoid of lysines on both chains. There are only tiny amounts produced of the M-chain negative, B-chain positive form. Because only two forms are separated by electrophoresis (the B-chain negative, M-chain positive form co-migrates with the tissue form and the small amount of the M-chain negative, B-chain positive form migrates with the ultimate conversion product), only two forms have been

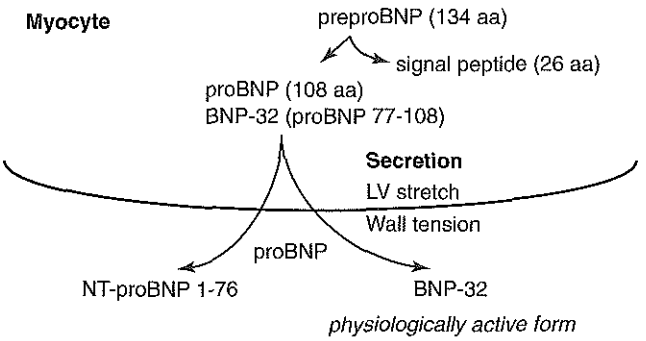

Figure 44-9 The biotransformation and release of BNP and NT-proBNP from the myocyte into the circulation (aa – amino acid).

used diagnostically and have been labeled CK-MB_2 and CK-MB_1.[35] The clearance rate of total CK activity from blood is a composite of the clearance rates of the individual isoforms.[1,2] The more prolonged half-lives are associated with the posttranslational degradation isoforms. Thus the orders of half-lives are CK-MM_1 > CK-MM_2 > CK-MM_3, and CK-MB_1 > CK-MB_2. Studies in an experimental animal model and in humans have shown that posttranslational modifications of isoforms occur in blood, are unidirectional, and do not occur in the lymphatic system or necrotic tissue.[3]

Early studies involving animal hearts or specimens obtained at autopsy from human hearts suggested a uniform distribution of CK-MB ranging from 5% to 50% of the total CK activity.[128] However, it has been shown that the proportion of CK-MB was 6% to 15% lower in the surrounding normal areas of tissue than in infarcted myocardium in humans. Further, in response to acute and chronic coronary artery occlusion in a dog model, myocardium showed twofold to threefold increases in CK-MB in both ischemic and nonischemic myocardium.[201,202] When studied more completely in humans, CK-MB concentrations ranged from 15% to 24% of total CK in myocardial tissue obtained from patients with left ventricular hypertrophy (LVH) caused by aortic stenosis, from patients with CAD without LVH, and from patients with CAD and LVH due to aortic stenosis. In contrast, patients with normal left ventricular tissue had a low percentage of CK-MB (<2%).[99] These data suggest that changes in the CK isoenzyme distribution are dynamic and occur in hypertrophied and diseased human myocardium. Diseased cells also have less total CK per cell.

Normal skeletal muscle, depending on its location, contains very little CK-MB.[128] Percentages as high as 5% to 7% have been reported, but <2% is much more common. There are some differences related to slow versus fast twitch muscle and thus to race. Severe skeletal muscle injury following trauma or surgery can lead to absolute elevations of CK-MB above the upper reference limit of CK-MB in serum. However, the percent CK-MB in serum would be low (percentages advocated vary but when comparing activity to activity, a percentage or <5% is often used and when one compares CK activity with CK-MB mass, a percentage of <2.5% is usually advocated).[128] Increases in serum total CK and CK-MB in several patient groups often present a diagnostic challenge to the clinician. Persistent elevations of serum CK-MB resulting from chronic muscle disease occur in patients with muscular dystrophy, end-stage renal disease, or polymyositis, and in healthy subjects who undergo extreme exercise or physical activities. The increase in serum CK-MB in runners, for example, may be related to the adaptation by the skeletal muscle during regular training and after acute exercise, resulting in increased CK-MB tissue concentrations.[25] The mechanism responsible for increased CK-MB in skeletal muscle following chronic muscle disease or injury is thought to be caused by the regeneration process of muscle, with reexpression of CK-MB genes similar to those found in the heart thus giving rise to increased CK-MB levels in skeletal muscle.[22,188] Thus skeletal muscle can become like heart muscle in its CK isoenzyme composition, with up to 50% CK-MB in some patients with severe polymyositis.

Myoglobin

Myoglobin is an oxygen-binding protein of cardiac and skeletal muscle with a molecular mass of 17,800 Da. The protein's low molecular weight and cytoplasmic location probably account for its early appearance in the circulation following muscle (heart or skeletal) injury. There is no difference in the myoglobin protein localization in the heart versus skeletal muscle. Increases in serum myoglobin occur after trauma to either skeletal or cardiac muscle, as in crush injuries or MI.[217] Serum myoglobin methods are unable to distinguish the tissue of origin, because the proteins are identical. Even minor injury to skeletal muscle may result in elevated concentrations of serum myoglobin, which may lead to the misinterpretation of myocardial injury. Since myoglobin is cleared renally, changes in GFR will cause increases. It has a very short half life of 10 minutes in blood.

Lactate Dehydrogenase Isoenzymes

Lactate dehydrogenase (LD) (MW 180,000 Da) is localized in the cytoplasm of tissue.[227] Even though LD isoenzymes are rarely used in clinical practice anymore, for historical purposes, their biochemistry will be described here. The highest activities of LD are found in skeletal muscle, liver, heart, kidney, and red blood cells. Electrophoresis on a variety of gels and buffer media, combined with kinetic and immunological studies, has provided convincing evidence of the existence of at least five isoenzymes, composed of four subunit peptides of two distinct types, designated M (for muscle) and H (for heart). LD-1 (H_4) moves the fastest toward the anode, while LD-5 (M_4) is closest to the cathode on an electrophoretic gel. LD-1 is found in highest concentrations in the heart, kidney (cortex), and red blood cells. LD-5 is found in highest concentrations in liver and skeletal muscle. The hybrid LD isoenzymes LD-2 (H_3M), LD-3 (H_2M_2), and LD-4 (HM_3) are also found in these and several other tissues. Because LD is not a tissue-specific enzyme, it is not surprising that serum total LD is increased in a wide variety of diseases. Studies have demonstrated that activities of total LD and LD-1 increase from right to left ventricles, with the H subunit activity varying twofold between different locations of the heart.[135] As with CK-2 in skeletal muscle, the heart-specific LD-1 isoenzyme in skeletal muscle can increase twofold (from 10% to 20% of total LD activity) during a 9 week period of exercise training, with parallel decreases in LD-5.[26] Thus one must be aware that acute and chronic injury incurred during exercise training and racing, increases in serum total LD, especially LD-1 and the ratio of LD-1 to LD-2. The tissue source of these increases is likely skeletal muscle as opposed to the myocardium.[24,26]

Some tests that may potentially become helpful clinical tools as biomarkers to detect atherosclerotic processes and

plaque vulnerability are listed in Boxes 44-6 and 44-7 and discussed later in this chapter.

C-Reactive Protein

CRP is an acute phase reactant initially developed to evaluate patients with infection.[179,193] It now appears that low concentrations (so called high sensitivity or hsCRP) can be a marker of the atherosclerotic process, as both chronic and acute atherosclerotic processes involve an inflammatory component (see Chapter 26). Among the ligands that can stimulate CRP are tissue necrosis factor (TNF) and interleukin 1 (IL-1), which are thought to stimulate IL-6 that then causes the elaboration of CRP from the liver (see Chapter 22). It is now clear that CRP itself can enhance the inflammatory and prothrombotic response. There are a large number of assays for hsCRP and a standard protocol for their reporting.

For primary prevention, values >3 mg/L are considered high risk. Recent data suggests that using hsCRP data with the calculated LDL is a potent way to predict risk. For risk stratification in primary prevention, the use of hsCRP routinely is not recommended by the AHA/CDC panel.[30] When used, <1 mg/L is considered low risk, 1 to 3 mg/L intermediate, and >3 mg/L high risk.

In patients who present with ACS, the initial value for hsCRP has prognostic significance. Whether it is short or long term depends on the study. In most studies, the influence of cardiac troponin measurements is the predominant short term prognostic factor and hsCRP adds to long term prognosis. However, this is not always the case. Of interest, hsCRP measurements, similar to BNP, seem to predict death but not recurrent infarction. This could be because of the effect of mortality, which can confound multivariable models, but it is different from the data in regard to cardiac troponin (see discussion later in this chapter).[107] It should be appreciated that once necrosis has occurred, hsCRP values rise and the ability to use them prognostically is attenuated.

BOX 44-6 Serological Biomarkers of Vulnerability Reflecting Metabolic and Immune Disorders

- Abnormal lipoprotein profile (high LDL, low HDL, abnormal LDL and HDL size density, Lpa)
- Nonspecific biomarkers of inflammation (hsCRP, CD40L, ICAM-1, VCAM-1, P-selectin)
- Serum biomarkers of metabolic syndrome (diabetes or hypertriglyceridemia)
- Specific biomarkers of immune activation (anti-LDL antibody, anti-HSP antibody)
- Biomarkers of lipid peroxidation (ox-LDL and ox-HDL)
- Homocysteine
- Pregnancy associated plasma protein-A
- Circulating apoptosis biomarker(s) (Fas/Fas ligand, not specific to plaque)
- ADMA/DDAH
- Circulating nonesterified fatty acids (e.g., NEFA)

hsCRP, High-sensitivity CRP; *CD40L,* CD40 ligand; *ICAM,* intracellular adhesion molecule; *VCAM,* vascular cell adhesion molecule; *MMP,* matrix metalloproteinases; *TIMP,* tissue inhibitors of MMPs; *LDL,* low-density lipoprotein; *HDL,* high-density lipoprotein; *HSP,* heat shock protein; *ADMA,* asymmetric dimethylarginine; *DDAH,* dimethylarginine dimethylaminohydrolase; and *NEFA,* nonesterified fatty acids.

BOX 44-7 Serological Biomarkers of Vulnerability Reflecting Hypercoagulability

- Markers of blood hypercoagulability (e.g., fibrinogen, D-dimer, and factor V Leiden)
- Increased platelet activation and aggregation (e.g., gene polymorphisms of platelet glycoproteins IIb/IIIa, Ia/IIa, and Ib/IX)
- Increased coagulation factors (e.g., clotting of factors V, VII, and VIII; von Willebrand factor; and factor XIII)
- Decreased anticoagulation factors (e.g., proteins S and C, thrombomodulin, and antithrombin III)
- Decreased endogenous fibrinolysis activity (e.g., reduced t-PA, increased PAI-1, certain PAI-1 polymorphisms)
- Prothrombin mutation (e.g., G20210A)
- Other athrombogenic factors (e.g., anticardiolipin antibodies, thrombocytosis, sickle cell disease, polycythemia, diabetes mellitus, hypercholesterolemia, hyperhomocysteinemia)
- Increased viscosity
- Transient hypercoagulability (e.g., smoking, dehydration, infection, adrenergic surge, cocaine, estrogens, postprandial, etc.)

t-PA, Tissue plasminogen activator; *PAI,* type 1 plasminogen activator inhibitor.

Serum Amyloid

Serum amyloid protein A is an acute phase protein, and an apolipoprotein has often been used with hsCRP in cross sectional studies. It can be synergistic with hsCRP[194] but is much less commonly used. At present, there is no standardized assay and no reference interval studies or consistent assay validations.

sCD40 Ligand

sCD40 ligand is a transmembrane protein related to TNF. It has multiple prothrombotic and proatherogenic effects. What is usually measured is the soluble form of the receptor, which has been shown to be a predictor of events after acute presentations.[218] At present, there is no standardized assay and no reference intervals studies or consistent assay validations.

Cytokines

There are a variety of stimulatory and inhibitory interleukins (TNF, IL-1, IL-6, IL-8, IL-12, IL-18) that are thought to help mediate the elaboration of CRP and the development of atherosclerosis and acute events. These cytokines either stimulate or inhibit leukocytes, often through T-cell mediated processes and effects on monocytes, which are indigenous to atherogenesis.[140] In some studies, IL-6 is more prognostic

than hsCRP. These cytokines often have inhibitors and/or binding proteins that modulate their effects. At present, there are no standardized assays and no normal range studies or consistent assay validations.

Myeloperoxidase

Myeloperoxidase is released when neutrophils aggregate and thus may indicate an active inflammatory response in blood vessels. It has been shown to be elevated chronically when chronic CAD is present.[238] It is increased when patients present with ACS.[43] Initial prognostic studies were encouraging but were done without adequate consideration of other analytes and specifically cardiac troponin.[42] Accordingly, additional studies are needed. At present, there is no standardized assay and no reference interval studies or consistent assay validations.

Phospholipase A2

Phospholipase A2 (Lp PLA2) is a phospholipase associated with LDL and is thought to be an inflammatory marker. It was previously known as platelet activating factor acetyl hydrolase (PAF). It is synthesized by monocytes and lymphocytes. It is thought to cleave oxidized lipids to induce lipid fragments that are more atherogenic and that increase endothelial adhesion. There is an FDA approved assay for this analyte with obligatory normal intervals. It has been shown to be predictive of events in a primary prevention cohort even when hsCRP is present in the model, suggesting it measures something different from the acute phase reactants associated with hsCRP.[31]

Pregnancy Associated Plasma Protein A

Pregnancy associated plasma protein A (PAPP-A) is a metalloproteinase expressed when IGF is freed from inhibition. It is thought to be expressed in plaques that may be prone to rupture. The literature in this regard is mixed at present concerning its use.[18,32,143] At present, there is no standardized assay and no reference interval studies or consistent assay validations.

Oxidized LDL

Oxidized LDL has been attributed a key role in the development of atherosclerosis (see Chapter 26). Several methods have been used to measure it, but they give potentially different data. Some have correlated malondialdehyde LDL with the development of atherosclerosis and short-term events.[94] Direct identification with antibodies suggests that oxidized LDL may be released from vessels and co-localize with Lp(a) after acute events.[213]

Placental Growth Factor

Placental growth factor is an angiogenic factor related to vascular endothelial growth factor (VEGF), which stimulates smooth muscle cells and macrophages. It also increases TNF and MCP-1. There is a novel assay for this analyte that is thought to provide additional prognostic information on patients who present with ACS.[92] At present, there is no standardized assay and no reference interval studies or consistent assay validations.

Matrix Metalloproteinases

Matrix metalloproteinases (MMP) can degrade the collagen matrix in either coronary artery or myocardium. They are integral to remodeling of the coronary artery and/or the heart after acute events. Elaboration of MMP 9, a gelatinase, is thought to be important in plaque destabilization and thus some have tried to measure it as a prognostic index.[110] Other MMPs participate in the elaboration of extracellular matrix in the heart. Many of the MMPs also have inhibitors (TIMPs) that modulate their effects. At present, there are no standardized assays and no normal range studies or consistent assay validations.

Monocyte Chemotactic Protein

Monocyte chemotactic protein (MCP-1) is a chemokine that is thought to be responsible for the recruitment of monocytes into atherosclerotic plaque (see Chapter 22). It has been reported to be elevated in patients with ACS and to have long-term predictive value.[65] However, at present, there is no standardized assay and no reference interval studies or consistent assay validations.

Tumor Necrosis Factor Alpha

Tumor necrosis factor alpha (TNFα) is an inflammatory cytokine and interleukin that is involved in the genesis of sepsis, arthritis, and a variety of other inflammatory states (see Chapter 22). It also has hemodynamic effects and reduces ventricular performance. It is also a common signaling molecule. Assays for it or its receptor have been developed, but the failure of recent therapeutic trials has led to concern about how to properly interpret the high levels seen in patients with CHF and coronary heart disease.[70] At present, there are no standardized assays and no reference interval studies or consistent assay validations.

Tissue Plasminogen Activator Antigen

Tissue plasminogen activator antigen (t-PA antigen and activity) and plasminogen activator inhibitor 1 (PAI-1). t-PA is the body's physiological fibrinolytic activator. PAI-1 is its endogenous inhibitor and binds to t-PA. Inhibition of fibrinolysis has been suggested to be a reason for recurrent infarction and the fact that maximal inhibition usually occurs in the early morning hours a reason for the circadian variability of AMI.[96] It may also be the reason why diabetics have such unstable disease since the growth factor properties of insulin stimulate increases in PAI-1.[209] An accurate assessment of this system includes both and some assessment of the bound compared with free levels.

Secreted Platelet Granular Substances

Both platelet factor 4 (PF4) and beta thromboglobulin (BTG) are secreted when platelets aggregate. PF4 has a short

half-life, is released by heparin, and is the cause of the antibodies that result in heparin-induced thrombocytopenia. BTG is not released by heparin and has a longer half-life. Both markers have been used to assess platelet aggregation.[87] BTG is by far the most reliable. At present, there are no standardized assays and no reference interval studies or consistent assay validations.

Isoprostanes

Isoprostanes are the end breakdown products of lipid peroxidation, and urinary levels have been used to assess the level of oxidative stress.[85,86] It is thought that oxidation of LDL is essential for the development of atherosclerosis and that HDL and other antioxidants work by antagonizing this oxidative stress. Urinary isoprostanes give one some summary assessment of this critical process. The most common ones measured are F_2-isoprostanes, but there are a large number of potential ones to measure. It does appear that they will eventually be helpful in assessing oxidative stress.

Urinary Thromboxane

Urinary thromboxane is the end metabolite of thromboxane A2, which is a measure of platelet aggregation. Urinary levels are elevated in patients with unstable coronary disease in keeping with the known participation of platelets in the pathogenesis of CAD. It is difficult to measure, and collecting urine in acute situation is at times problematic.

Adhesion Molecules

Adhesion molecules are a wide variety of molecules that can potentially be measured as a way of assessing the adherence of leukocytes and/or platelets or other adhesive proteins to the endothelial matrix.[136] Some are receptors. Some of the examples include PECAM-1 (platelet-endothelial adhesion molecule 1), P-selectin, e-selectin, and VCAM-1 (vascular cell adhesion molecule 1). At times, the receptor itself is measured but often it is a soluble portion that circulates that is the ligand. At present, there are no standardized assays and no reference interval studies or consistent assay validations.

Other Proposed Markers

Several markers of ischemia have been proposed but are yet to be validated.

Ischemia Modified Albumin

Ischemia modified albumin (IMA), measured by the albumin cobalt binding test, has been approved by the FDA for its negative predictive value in concert with a normal ECG and a normal cardiac troponin. This test relies on changes in the binding of cobalt to the albumin molecule when ischemia is present.[207] It requires additional validation of the meaning of a positive test before clinical use for ruling in ischemia.

Choline

Choline is released after stimulation by phospholipase D and has been touted as a test of prognosis in patients with chest discomfort.[61] At present, there is no standardized assay and no reference interval studies or consistent assay validations.

Unbound Free Fatty Acid

Unbound free fatty acid (uFFA) has also been touted as a marker of ischemia. Most fatty acid is bound and ischemia is thought to increase the small unbound fraction. Initial studies have reported mixed results.[4] At present, there is no standardized assay and no reference interval studies or consistent assay validations.

Nourin

Nourin I is a small protein released rapidly by "stressed myocytes." It induces changes in a variety of inflammatory cytokines and attracts neutrophils. Preliminary studies have been done attempting to validate its use.[53] At present, there is no standardized assay and no reference interval studies or consistent assay validations.

ANALYTICAL MEASUREMENT OF CARDIAC PROTEINS

The analytical techniques used to measure the most commonly used cardiac biomarkers are reviewed here. All of the initial cardiac markers were enzymes, so the earliest techniques measured the catalytic activity of the marker. Immunoassay techniques measure the mass of a marker and they are the predominant methodology used in clinical laboratory practice today. Analytically, they offer lower limits of detection, improved precision, and faster assay times, on both highly automated central laboratory platforms and POCT.

Cardiac Troponin

Methodology

Cummins and co-workers were the first to develop a radioimmunoassay to measure cTnI that used polyclonal anti-cTnI antibodies.[60] Although the assay showed approximately 2% cross-reactivity with skeletal TnI, it still had excellent clinical specificity for cardiac muscle injury. The assay was never automated or developed for commercial use. The first monoclonal ELISA, anti-cTnI antibody-based immunoassay, was described by Bodor et al.[37] This assay has less than 0.1% cross-reactivity with skeletal TnI, but it was not suited for clinical use because of the lengthy assay time. Over the past 15 years, numerous manufacturers have described the development of monoclonal antibody–based diagnostic immunoassays for the measurement of cTnI in serum.[18,54] Assay times range from 5 to 30 minutes. As shown in Table 44-1, over a dozen assays have been approved by the FDA for patient testing within the United States on central laboratory and POCT platforms. In addition to these quan-

titative assays, several assays have been FDA approved for the qualitative determination of cTnI.

In practice, two obstacles limit the ease for switching from one cTnI assay to another. First, there is currently no primary reference cTnI material available for manufacturers to use for standardizing their assays. Second, assay concentrations fail to agree because of the different epitopes recognized by the different antibodies used. An effort has been underway since 2001 by the AACC Subcommittee on Standardization of cTnI to prepare a primary reference material.[50] In collaboration with the National Institute for Standards and Technology (NIST), two reference materials—a TIC ternary complex and an IC binary complex—have been identified. Working with NIST and the in vitro diagnostic industries, preliminary round robin studies have demonstrated that while standardization of assays remains elusive, harmonization of cTnI concentrations by different assays has been narrowed from a twentyfold difference to a twofold to threefold difference.

cTnI is present in the circulation in three forms: (1) free, (2) bound as a two-unit binary complex (cTnI-cTnC), and (3) bound as a three-unit ternary complex (cTnT-cTnI-cTnC).[113] Thus different assays do not produce equivalent concentration results, and comparisons of absolute cTnI concentrations in clinical studies cannot and should not be made. Comparisons between assay systems must view changes as relative to each assay's respective upper reference limit. Users must understand the analytical characteristics of each troponin I assay before clinical implementation.

Several adaptations of the Roche Diagnostics (Indianapolis) cTnT immunoassay have been described, resulting in an FDA-approved third-generation assay available worldwide.* Two monoclonal anticardiac troponin T antibodies are used in the third-generation assay. Skeletal muscle TnT is no longer a potential interferent, as was found in the first-generation ELISA cTnT assay.[234] In contrast to cTnI, no standardization bias exists for cTnT because the same antibodies (M11, M7) are used in both the central laboratory and POC quantitative and POC qualitative assay systems.

Surveys on cardiac troponin use have been conducted[13] but the data in the peer-reviewed literature are negligible. The distribution of cardiac troponin assays used as reported over the past several years by the College of American Pathologists surveys is listed in Table 44-2. cTnI assay usage accounts for 89% (number of vendors) and cTnT (1 vendor) for 11%. POCT assays account for approximately 10% of all testing.

In 2001, the IFCC Committee on Standardization of Markers of Cardiac Damage (C-SMCD) established recommended quality specifications for cardiac troponin assays.[176] These specifications were intended for use by the manufacturers of commercial assays and by clinical laboratories using troponin assays. The overall goal was to attempt to establish uniform criteria in order that all assays could be evaluated objectively for their analytical qualities and clinical performance. Both analytical and preanalytical factors were addressed as shown in Box 44-8. First, an adequate description of the analytical principles, method design, and assay components needs to be made. This includes the following recommendations:

*References 11, 54, 55, 77, 113, 115, 234.

BOX 44-8 Quality Specifications—Cardiac Troponin Assays

A. Analytical Factors

1. Antibody specificity—recognize epitopes as part of molecule and equimolar for all forms
2. Influence of anticoagulants
3. Calibrate against natural form of molecule
4. Define type of material useful for dilutions
5. Demonstrate recovery and linearity of method
6. Describe detection limit and imprecision (10% CV)
7. Address inferents, i.e., rheumatoid factor, heterophile antibodies

B. Preanalytical Factors

1. Storage time and temperature conditions
2. Centrifugation effects—gel separators
3. Serum–plasma–whole blood correlations

Modified from Panteghini M, Gerhardt W, Apple FS, Dati F, Ravkilde J, Wu AH. Quality specifications for cardiac troponin assays. Clin Chem Lab Med 2001;39:174-8.

First, the antibody specificity as to what epitope locations are identified needs to be delineated. Epitopes located on the stable part of the cTnI molecule should be a priority. Further, assays need to clarify whether different cTnI forms (i.e., binary versus ternary complex) are recognized in an equimolar fashion by the antibodies used in the assay. Specific relative responses need to be described for the following cTnI forms: free cTnI, the I-C binary complex, the T-I-C ternary complex, along with oxidized, reduced, and phosphorylated isoforms of the three cTnI forms. Further, the effects of different anticoagulants on binding of cTnI need to be addressed.[76]

Second, the source of material used to calibrate cardiac troponin assays, specifically for cTnI, should be reported. Currently a cTnI standardization subcommittee of the AACC is addressing the use of several materials to develop a primary reference material that will assist in at least harmonizing cTnI concentrations across different assays.[50,113] Because antibody differences will always be present in different assays, complete standardization will never be possible for cTnI. However, for cTnT, because there is only one assay manufacturer (Roche Diagnostics), standardizing between assay generations has been consistent.

Third, assays need to describe methods used for obtaining minimal detection limits (e.g., mean plus 3 SD of 20 replicates of a zero calibrator) and total imprecision, describing at what concentration a 10% CV is attained. Preanalytical factors that should be described include the effects of storage time and temperature, glass versus plastic tubes and gel separator tubes, and the influence of anticoagulants and whole blood measurements. As more assay systems are devised for POCT, the same rigors applied to the central laboratory methodologies need to be adhered to by the POCT systems.

While clinicians and laboratorians continue to publish guidelines supporting TATs of <60 minutes for cardiac biomarkers, the largest TAT study published to date has demonstrated that TAT expectations are not being met in a large percentage of hospitals. A CAP Q probe survey study of 7020 cardiac troponin and 4368 CK-MB determinations in 159 hospitals demonstrated that the median and 90th percentile TAT for troponin and CK-MB were as follows: 74.5 minutes and 129 minutes; and 82 minutes and 131 minutes, respectively.[171] Less than 25% of hospitals were able to meet the <60 minute TAT, representing the biomarker order-to-report time. Unfortunately a separate subanalysis of just POCT systems was not reported. However, preliminary data have shown that implementation of POC cardiac troponin testing can decrease TATs to <30 minutes in cardiology critical care and short stay units.[162] These data highlight the continued necessity for laboratory services and healthcare providers to work together to develop better processes to meet a <60-minute TAT as requested by physicians.

Reference Intervals

If possible, each laboratory should determine a 99th percentile of a reference group for cardiac troponin assays with the specific assay used in clinical practice or validate the assay

based on findings in the literature.[16] Further, acceptable imprecision (coefficient of variation and percent of CV) of each cardiac troponin assay (Figure 44-10) and for CK-MB mass assay has been defined as ≤10% CV at the 99th percentile reference limit.[178]

Unfortunately the majority of laboratories do not have the resources to perform adequately powered reference interval studies nor the ability to carry out NCCLS protocols to establish total imprecision criteria for every cardiac troponin assay in the marketplace. Therefore clinical laboratories have to rely upon the peer-reviewed published literature to establish reference intervals. Numerous reference studies have been carried out for specific cardiac troponin assays. When reviewing these studies, caution must be taken when comparing the findings reported in the manufacturer's FDA-approved package inserts, with the findings reported in journals because of differences in total sample size, distributions by gender and ethnicity, age ranges, and the statistic used to calculate the 99th percentile given. To date, very few in vitro diagnostic companies have published their 99th percentile cutoffs in their package inserts. There is no established guideline set by the FDA to mandate a consistent evaluation of the 99th percentile reference limit for cardiac troponins. The largest and most diverse reported reference interval study to date shows plasma (heparin) 99th percentile reference limits for eight cardiac troponin assays (seven cTnI, one cTnT) and seven CK-MB mass assays (Tables 44-3 and 44-4).[16] These studies were performed in 696 healthy adults (age range 18 to 84 years) stratified by gender and ethnicity. The data, while generally in agreement with information provided by personal communication with the manufacturer, demonstrate several issues. First, two cTnI assays show a 1.2- to 2.5-fold higher 99th percentile for males versus females. Second, two cTnI assays demonstrated a 1.1- to 2.8-fold higher 99th percentile for African Americans versus Caucasians. Third, there was a thirteenfold difference between the lowest versus the highest measured cTnI 99th percentile limit. Obviously the lack of cardiac troponin assay standardization (there is no primary reference material available) and the differences in antibody epitope recognition between assays (different assays use different antibodies) give rise to substantially discrepant results. What is generally recognized, though, as long as one understands the characteristics of an individual assay and does not attempt to compare absolute concentrations between different assays, is that clinical interpretation should be acceptable for all assays.

How to implement reference cutoffs for cardiac troponin is not clear at present. Since only one or two of the more than dozen commercially available assays can attain a total 10% CV at the 99th percentile, caution must be used in implementing a diagnostic cutoff that may potentially give

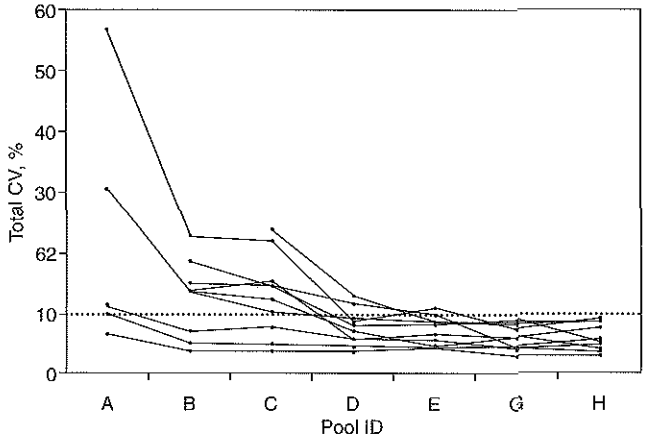

Figure 44-10 Cardiac troponin I imprecision profiles for human serum pools using different cTnI assays, with 10% CV concentration indicated by the dashed line. *(From Panteghini M, Pagani F, Yeo KT, Apple FS, Christenson RH, Dati F, et al. Evaluation of the imprecision at low range concentrations of the assays for cardiac troponin determination. Clin Chem 2004;50:327-32.)*

false-positive analytical results. Many studies have addressed the total imprecision of cardiac troponin assays, including what the lowest concentration will be to attain a 10% CV. The manufacturers continue to publish package insert data, primarily based on within-run or within-day precision. Again, there is no consistent FDA specification regarding what precision value should be reported on the package insert. To better address day-to-day clinical laboratory practice, the IFCC C-SMCD has published findings demonstrating the total imprecision for 13 commercial assays, based on a 20-day NCCLS protocol.[178] None of the assays were able to experimentally achieve a 10% CV at their 99th percentile cutoff. Therefore to avoid the potential for false-positive diagnostic criteria based on cardiac troponin monitoring at the 99th percentile, a group of experts in both the laboratory medicine and cardiology communities initially endorsed the concept that until cardiac troponin assay imprecision improves at the low end, the lowest concentrations to attain a 10% CV should be used as a modified ESC/ACC diagnostic cutoff for detection of myocardial injury.[18,19,73] The ultimate goal will be to have all cardiac troponin assays attain a 10% CV at the 99th percentile reference limit. However, when using serial troponin determinations and a 99th percentile cutoff, assay imprecision differences at will misclassify less than 1% of patients ruling out for myocardial infarction. Therefore all biomarker increases above the 99th percentile should be interpreted cautiously, within the clinical context of the patient, and followed up with serial samples over a 6- to 12-hour period after presentation.[6,103]

Use of the 2000 ESC/ACC redefinition of MI consensus document, which is predicated on cardiac troponin monitor-

ing, has already demonstrated an increase in the number of MIs in (1) day-to-day clinical practice, (2) emergency departments, (3) epidemiologic departments, (4) clinical trials, (5) society, and (6) public policy.[225] Characteristics used to define a disease in one country may be interpreted differently by clinicians in another nation, thus possibly rendering comparison of cardiac disease between countries difficult but not impossible. Consequentry the AHA, the World Heart Federation Councils on Epidemiology and Prevention, the Centers for Disease Control and Prevention, and the National Heart, Lung, and Blood Institute have jointly published a statement that defines acute coronary heart disease (CHD) in epidemiology and clinical research studies.[142] This statement was based on a systematic review of evolving diagnostic strategies with the goal of developing standards for population studies of CHD. The definition of CHD cases was deemed dependent on symptoms, signs, ECG, and/or autopsy findings and biomarkers. Cardiac biomarkers, measures of myocardial necrosis, were prioritized for use as follows: cardiac troponin > CK-MB mass > CK-MB activity > CK. An adequate set of biomarkers was determined to be at least two measurements of the same biomarker at least 6 hours apart (similar to the preestablished ESC/ACC consensus). A diagnostic biomarker was, at least, one positive biomarker in an adequate set showing a rising or falling pattern in the setting of clinical ischemia and the absence of noncardiac causes of biomarker elevation. An equivocal biomarker was when only one available measurement was positive, but not in the clinical setting of ischemia or in the presence of nonischemic causes. A positive biomarker was defined as exceeding the 99th percentile or the lowest concentration at which a 10% CV can be demonstrated.

For clinical trials, to avoid the confusion of multiple centers using multiple assays, several approaches are recommended for using cardiac troponin testing.[18,167] First, all samples from trial centers should be analyzed in a core, central lab—with a precise, well-defined assay. Second, all trial centers should be provided with the same well-defined assays. Third, each center's assays should be uniformly defined using the 10% CV concentration (assay-dependent), thus not relying on local lab criteria and troponin cutoffs. Fourth, a multiple (twofold to threefold) of the 10% CV cutoff value should be used. Fifth, the degree of variability should be reported if those conducting trials decide to use cutoff values defined in earlier studies.

The advances in diagnostic technology in the development of improved low-end analytical detection of cardiac troponins have begun to impact the prevalence of acute MI detection. Increasingly, the data suggest that the more sensitive cardiac troponin tests result in greater rates of MI diagnosis and greater rates of cardiac troponin positivity compared with other markers.[124,134,142] Milder and smaller MIs will be detected. Clinical cases that were earlier classified as UA will be given a diagnosis of MI (because of an increased cardiac troponin), and now procedure-related troponin increases (i.e., following angioplasty[6,93,175]) will be labeled MI. The importance of small troponin increases has been confirmed by their association with a poor prognosis (this will be discussed later in the Risk Stratification section of this chapter). Table 44-5 demonstrates, based on several studies that compared CK-MB and cardiac troponin assays in ACS patients, that a substantial increase in the rate of MIs, ranging from 12% to 127%, was detected. In one of the studies by Lin et al, a subset (5%) of cTnI-negative, CK-MB-positive patients revealed the potentially underlying false-positive MI rate when using CK-MB as a standard for MI detection.[134] This was likely caused by release of CK-MB from skeletal muscle, in the absence of myocardial injury. Further, a subset (12%) of cTnI-positive, CK-MB-negative patients showed a subset of MIs that would not have been detected without cardiac troponin monitoring. Additional studies also have clearly demonstrated the impact of lowering diagnostic cutoff concentrations from the ROC curve, to the 10% CV value or to the 99th percentile limit. Table 44-6 contains representative data showing a 125% increase in the negative CK-MB, but a positive cardiac troponin patient group of ACS patients predicated on a changing standard of what cardiac troponin cutoff is used. Kontos et al also showed a similar incidence for increased MI, with the prevalence increasing from 7.8% using CK-MB to 28% to 195% using various lower cTnI diagnostic values.[124] All these data, taken together, support the implementation of cardiac troponin in place of, not in combination with, CK-MB.

Brain Natriuretic Peptide

Methodology

Box 44-9 shows both current assays and future assay development for BNP or NT-proBNP. Limited licensing agreements have apparently restricted BNP assay development to Shionogi (RIA, not FDA approved), Biosite (Triage POC, FDA approved), Abbott (AxSYM, FDA approved), Bayer (Centaur, FDA approved), and Beckman (Biosite assay performed on Access, FDA approved). Roche (Elecsys, FDA approved), which manufactures NT-proBNP, has (as of

this writing) sublicensed Dade-Behring (Dimension, FDA approved) and DPC and Ortho-Clinical Diagnostics. Characteristics of the commercial assays differ as to standardization of measurements and use of antibodies. Differential recognition of epitope regions appears to be the major determinant in BNP and NT-proBNP stability for each assay. Assays that use an antibody that recognizes the N-terminus labile region of BNP (Biosite, Beckman, Abbott) demonstrate less analyte stability at room temperature (≤4 hours) than assays that use one of their antibodies recognizing the C-terminus (Bayer). The Roche NT-proBNP antibody configuration allows for 72 hours of sample stability at room temperature. At present, reference materials are not available for either BNP or NT-proBNP, and standardization is yet to be achieved. However, for NT-proBNP, which Roche has licensed to multiple diagnostic companies, because reagents and antibody materials will be equivalent, concentrations measured between assays should be harmonized. Further information is needed to better document what NP fragments are measured in the NT-proBNP assay. For BNP, different materials have been used to calibrate different assays, and as described above, different antibody pairs are used in each assay. However, it appears that both Abbott and Bayer have set their assays to be comparable around the 100 pg/mL BNP concentration, the concentration with the largest evidence-based clinical information used for diagnostic purposes. Therefore, since neither NT-proBNP or BNP assay systems use a primary reference material to calibrate their assays, results should be reported in nanograms per liter (ng/L) concentration units and not picomoles per liter.

Stability of BNP immunoreactivity is compromised in whole blood collected in glass tubes versus plastic and siliconized tubes.[203,204] This has been described by all assay manufacturers, with 30% to 80% loss of immunoreactivity in glass after 4 to 8 hours. Further, proBNP has been shown to be more stable than its metabolized form of BNP, which is the 32–amino acid form measured by BNP immunoassays. Further studies regarding the immunoreactivity of proBNP and thus half-life differences are needed by each BNP commercial assay to better elucidate the clinical utility if any for proBNP in CHF patients. Imprecise implications also should be better understood and studied regarding different assays.[236] Quality specifications are available for BNP assays.[15A]

Reference Intervals

There are several practical issues regarding the use of serum/plasma/whole blood monitoring of BNP and NT-proBNP. First, reference intervals vary depending on which assay is used and the nature of the reference population used (Tables 44-7 and 44-8). Second, a number of clinical factors affect the BNP and NT-proBNP concentrations, most importantly age, gender, and renal function. Significant differences are observed between men and women (higher) and with increasing concentrations with age by decade, as shown in Figure 44-11. Third, for BNP and NT-proBNP,[204,210] the relative impact of these factors in relation to the degree of

left ventricle dysfunction remains a debate. When BNP concentrations are monitored in ages >60 years and reference concentrations >100 pg/mL, the cutoff that has demonstrated a high-negative predictive value (NPV) in ruling out CHF has been described. Increased NT-proBNP concentrations above 400 pg/mL in the >60 years population present the same diagnostic dilemma. For both analytes, there is an inverse relationship between values and body mass index. For NT-proBNP, establishing reference intervals has been challenging. Review of both the FDA approved U.S. package insert and the European assay package insert reveals substantial differences in what concentrations are considered normal by age and sex.

Creatine Kinase-2 and Isoforms

Methodology

CK-2 levels are measured in numerous ways.[28,233] The present discussion will concentrate on the immunoassays that use monoclonal anti-CK-2 antibodies.[107-109] Immunoassays developed in recent years have improved on the analytical and clinical sensitivity and specificity of the earlier immunoinhibition and immunoprecipitation assays. These assays now (1) measure CK-2 directly and provide mass measurements, (2) are easily automated, and (3) are rapid (≤30 minutes). This allows laboratories the ability to offer more testing services 24 hours a day, 7 days a week (24/7). This service improvement enhances the clinician's ability to triage patients from intensive to nonintensive care beds and to discharge patients who have not had an AMI. Mass assays reliably measure low CK-2 concentrations in samples with low total enzyme activity (<100 U/L) and with high total enzyme activity (>10,000 U/L). Further, no interferences from other proteins have been documented. The majority of commercially available immunoassays that use monoclonal anti-CK-2 antibodies are the same as those listed in Table 44-1 for cardiac troponin assays. Excellent concordance has been shown between mass concentration and activity assays.[68] All have detection limits of approximately 1 μg/L, are 100% specific for CK-2, and are remarkably similar in clinical performance in the diagnosis of AMI. Analytical performance, linearity, and cost may vary between assays. One of the many impacts these immunoassays provide is that serum CK-2 concentrations can be determined conveniently at almost any time of day, without additional laboratory personnel. The diagnostic cutoff is assay-dependent because of a lack of CK-2 standardization between different manufacturers. A CK-MB Standardization Subcommittee of the AACC has been successful in developing, testing, and validating a primary reference material that is commercially available to assist in harmonization.[51] If used for assay standardization, this material allows concentrations to be reported within 20% of each other. Trends documented in the College of American Pathologists surveys for CK-2 quantitation show during the past 5 to 10 years a large shift to the predominant use of monoclonal anti-CK-2 antibody-based mass assays (>80%).

At present, rarely are isoforms routinely measured in the clinical laboratory. Historically, they were widely used as a research tool, but never gained clinical acceptance. Several technologies have been applied to separate and quantitate the various CK-2 isoforms. These include isoelectric focusing, chromatofocusing, immunoblotting, anion-exchange high-performance liquid chromatography (HPLC), and electrophoresis.[29,183] Their major disadvantages have been

lengthy assay time, lack of sensitivity in the very low CK range, and the inability to easily incorporate a technique into a clinical laboratory throughout a 24-hour day. A high-voltage electrophoresis procedure has been developed that provides rapid and sensitive enough results to permit CK-2 isoform measurement within the reference interval of total CK.[52]

Advances in the production of monoclonal antibodies have not provided the means for the development of rapid and sensitive immunoassays for CK-3 and CK-2 isoform quantitation.[52] Proper specimen collection and stabilization of CK-2 isoforms are essential for the correct measurement of the CK-2_2 and CK-2_1 isoforms. A progressive increase in posttranslational degradation of CK-2_2 to CK-2_1 has been observed at room temperature. Incorporation of EDTA at a final concentration of 5 to 15 mmol/L to blood has been shown to stabilize the isoform distribution.

Reference Intervals

For CK-MB, as has been recognized for years for total CK,[228] all assays demonstrate a significant 1.2- to 2.6-fold higher 99th percentile for males versus females. Further, there were four assays that showed higher, up to 2.7-fold, concentrations for African Americans versus Caucasians. These data demonstrate that clinical laboratories must consider establishing different CK-MB reference cutoffs for at least men versus women.[16,228]

Myoglobin

Myoglobin has been measured in serum by RIA, latex agglutination, and two-site immunoassay based on monoclonal antibodies.[177,217] Historically, polyclonal antibody–based immunoassays, while sensitive and specific, lacked laboratory and clinical acceptance because of the lengthy assay time (2 hours). Although early latex agglutination assays provided more rapid turnaround times (30 minutes), the assays were semiquantitative. Rapid and quantitative nephelometric (15 to 30 minutes), turbidimetric[47] (2 minutes), and fluorescence (8 minutes) immunoassays[206] have been commercialized that incorporate monoclonal antibodies. Each of these techniques has good analytical performance. Immunoassay analysis times have substantially decreased with improved technology, which allows for measurements on both central laboratory and POCT. Since variability among commercial myoglobin assays exists, the IFCC C-SMCD organized an international collaborative study to identify candidate secondary reference materials. A single lyophilized, isolated human heart myoglobin material prepared in human serum was selected and has demonstrated a bias reduction between numerous commercial myoglobin assays from 32% to 13%, and established a basis for the selection of a recognized reference material.[177] Reference intervals for serum myoglobin vary according to age, race, and sex. On the average, as serum concentrations increase with age, men have higher concentrations than women, and African Americans have higher concentrations than Caucasians. For consistency with cardiac troponin and CK-MB, the 99th percentile of a reference population should be used as the reference cutoff.

Lactate Dehydrogenase Isoenzymes

The measurement of total LD has always been enzymatic (see Chapter 21). The complete spectrum of isoenzymes is determined after separation by electrophoresis. There are some inhibition techniques that measure LD-1 without separating the other isoenzymes. There also are monoclonal-based assays for determination of HBD, which consists of LD-1 and LD-2.

CLINICAL UTILITY

The ideal marker of myocardial injury should (1) provide early detection of injury, (2) provide rapid diagnosis for an acute MI, (3) serve as a risk stratification tool in ACS patients, (4) assess the success of reperfusion after thrombolytic therapy, (5) detect reocclusion and reinfarction, (6) determine the timing of an infarction and infarct size, and (7) detect procedural related perioperative MI during cardiac or noncardiac surgery. Before discussing the detailed changes in serum cardiac biomarkers following AMI, it is beneficial to review the diagnostic logic used by the ED physicians or attending clinicians (typically cardiologists) when faced with making a diagnosis. Ruling out AMI requires a test with high diagnostic specificity (preferred by the ED physician in the urgent care setting) whereas ruling in AMI requires a test with high diagnostic sensitivity (preferred by the cardiologist following admission). Diagnostic strategies often require different decision thresholds (cutoff points) for different cardiac biomarkers. It is the function of the laboratory to provide advice to physicians about cardiac biomarker characteristics. Figure 44-12 shows the classic rise and fall patterns of myoglobin, CK-MB, and cardiac troponin over a 7-day period following onset of acute MI.

Patients present to EDs or other primary care providers with a multitude of clinical signs and symptoms in which the differential diagnosis of acute myocardial infarction (AMI and heart attack) is considered. Figure 44-13 demonstrates the complete spectrum of clinical presentations of such a patient. The spectrum encompasses on one end the patient presenting with ischemia, without myocardial cell death (necrosis) or ECG alterations. The other end of the spectrum represents the patient presenting with ECG evidence of AMI indicated by an ST-elevation or Q-wave ECG finding. The entire spectrum of clinical presentations has been designated ACS. To assist in differentiating patients with AMI from non-AMI, the European Society of Cardiology/American College of Cardiology (ESC/ACC) has published consensus guidelines for the redefinition of AMI.[6,58,59,121] A cornerstone of the redefinition is predicated on cardiac biomarkers, specifically cTnI or cTnT. Boxes 44-2 to 44-4 summarize the definition of MI as defined by the ESC/ACC consensus.[6,103] The following are designated as

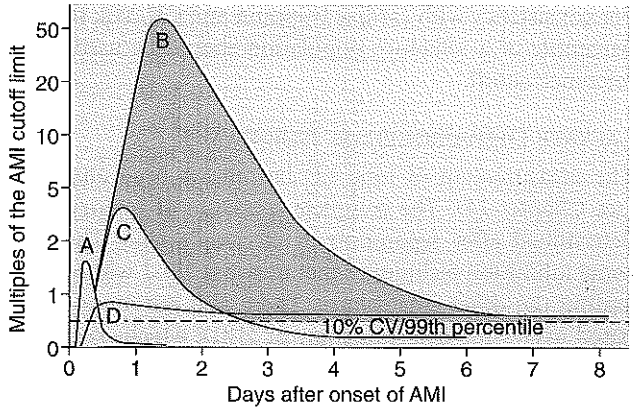

Figure 44-12 Classic rise and falling pattern of cardiac biomarkers from onset of acute myocardial infarction: **A,** myoglobin; **B,** cardiac troponin; **C,** CK-MB; **D,** cardiac troponin following minor injury.

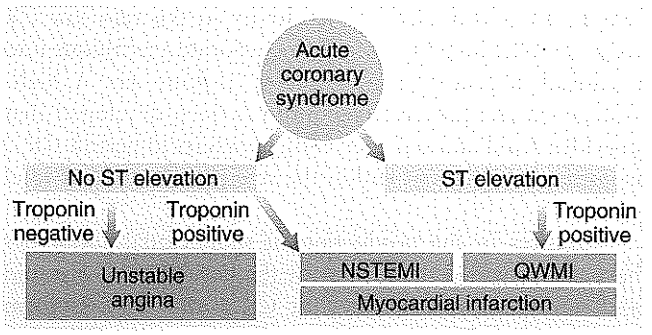

Figure 44-14 The distinction between non-ST elevation myocardial infarction and unstable angina predicated on an increased cardiac troponin in patients presenting with ischemic discomfort. *(Data from Brennan ML, Penn MS, Van Lente F, Nambi V, Shishehbor MH, Aviles RJ, et.al. Prognostic value of myeloperoxidase in patients with chest pain. N Engl J Med 2003;349:1595-604.)*

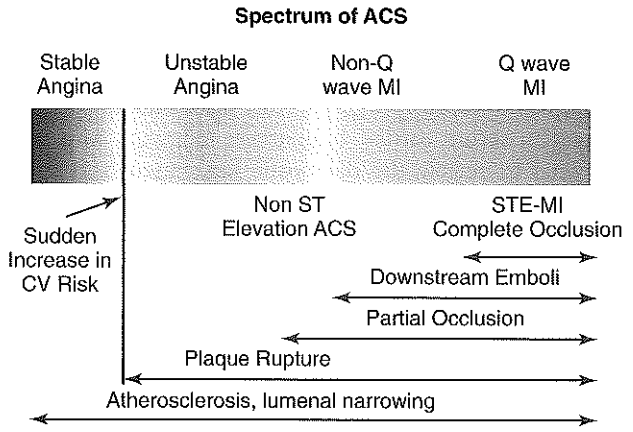

Figure 44-13 Complete spectrum of acute coronary pathophysiological process from initiation of atherosclerosis to cell death. *(From Personal Communication Robert Jesse, MD.)*

biochemical indicators for detecting myocardial necrosis: (1) a maximal concentration of cTnI or cTnI exceeding the decision limit, defined as the 99th percentile of values for a reference control group, on at least one occasion during the first 24 hours after the index clinical event; (2) a maximal value of CK-MB (preferably mass) exceeding the 99th percentile of values for a reference control group on two successive samples or a maximal value exceeding twice the upper reference limit during the first hours after the index clinical event (although the consensus document states values for CK-MB should rise and fall, either a rising or falling pattern should be considered diagnostic; however, values that remain elevated without change are rarely caused by MI; and (3) in the absence of availability of a cardiac troponin or CK-MB assay, total CK greater than two times the upper reference limit may be employed. In addition to the ESC/ACC consensus document for redefining MI, the ACC/American Heart Association (AHA) guidelines for management of UA recommend monitoring cardiac troponin in ACS patients for differentiating UA (defined as when cardiac troponin is within the 99th percentile reference limit) and NSTEMI (defined as when cardiac troponin is increased above the 99th percentile reference limit), as shown in Figure 44-14.[40,42]

Several markers should no longer be used to evaluate cardiac disease. They include aspartate aminotransaminase (AST), total creatine kinase activity (CK), total lactate dehydrogenase (LD), and LD isoenzymes with the exception of hydroxyl butyrate dehydrogenase (HBD), which some clinicians use to estimate infarct size. These markers have poor specificity for the detection of cardiac injury because of their wide tissue distribution. Because total CK and CK-MB have been utilized for so many years, some laboratories may continue to measure them to allow for comparisons with cardiac troponin over time before discontinuing use of CK. In addition, the use of total CK in developing countries may be the preferred and only alternative for financial reasons. This concept is emphasized in a statement from the AHA Council on Epidemiology and Prevention regarding case definitions for acute CHD in epidemiology and clinical research studies.[142] To more accurately interpret recent trends in heart disease, specifically AMI, during the spread of new technology and a new definition of AMI predicated on cardiac troponin, the following recommendations were made: (1) simultaneous use of old biomarkers with cardiac troponin should be used to determine the effects of new biomarkers, and (2) the use of adjustment factors should be considered in databases and retrospective studies seeking to determine incidence and trends of AMI before and after cardiac troponin–derived research studies.

The cardiology recommendations imply that for clinical laboratories that cannot move as rapidly as others to imple-

ment the new cardiac troponin standard, CK-MB (preferable mass) should be used. Although it is suggested that CK-MB be used together with cardiac troponin for (1) assisting in timing of onset of myocardial injury, (2) infarct sizing, or (3) determination of reinfarction, at present there is no strong evidence to support dual testing for cTn and CK-MB. Therefore, for monitoring ACS patients to assist in clinical classification, cardiac troponin is the preferred biomarker. However, it has been observed that in practice clinicians still request CK-MB monitoring to assist in timing of patient presentation and to assist in determining a baseline value in patients with NSTE AMI who have an incidence of reinfarction of between 10% and 15%. In a recent series of cases examining in-hospital reinfarctions (extensions), CK-MB testing was of no added value. Consequently, in practice, each institution will have to weigh the cost-benefit (clinical) ratio regarding using both cardiac troponin and CK-MB testing.

For the majority of patients, blood should be obtained for testing at hospital admission (0 hours), at 6 to 9 hours, and again at 12 to 24 hours if the earlier specimens are normal and the clinical index of suspicion is high. For patients in need of an early diagnosis that will parallel a rapid triage protocol, a rapidly appearing biomarker, such as myoglobin, has been suggested to be added to serial cardiac troponin monitoring. In practice, it appears that the majority of hospitals throughout the world do not use myoglobin as an early marker. However, some early evidence suggests a potential role for multimarker testing that includes myoglobin for risk stratification in chest pain units[12,168] and for exclusion of MI.[150]

GENERAL BIOMARKER OBSERVATIONS

Cardiac Troponin

Several general clinical impressions can be made regarding cardiac troponin I and T. First, the early release kinetics of both cTnI and cTnT are similar to those of CK-MB after AMI, with increases above the upper reference limit seen at 2 to 6 hours (Figures 44-12 and 44-15). The initial increase is due to the 3% to 6% cytoplasmic fraction of troponin (CK-MB is 100% cytoplasmic). Second, cTnI and cTnT can remain increased up to 4 to 14 days after AMI. The mechanism is likely the ongoing release of troponin from the 94% to 97% myofibril-bound fraction. The long interval of cardiac troponin increase is responsible for it replacing the LD isoenzyme assay in the detection of late-presenting AMI patients. Third, the very low to undetectable cardiac troponin values in serum from patients without cardiac disease (normal and healthy reference population) permit use of lower discriminator concentrations compared with CK-MB for the determination of myocardial injury. Finally, cardiac tissue specificity of cTnI and cTnT should eliminate false clinical impression of AMI in patients with increased CK-MB concentrations following skeletal muscle injuries.[21]

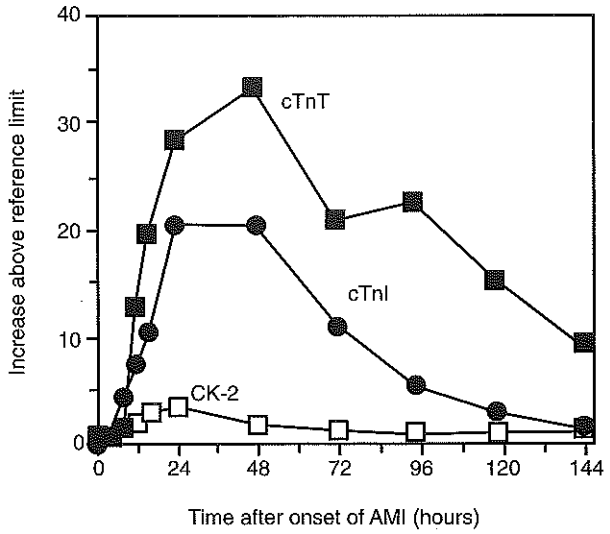

Figure 44-15 Serial serum creatine kinase-2 (CK-MB), cardiac troponin I (cTnI), and cardiac troponin T (cTnT) profiles after AMI. Cardiac markers are plotted as multiples of the upper reference limit.

Numerous clinical studies involving cTnI and cTnT have been published pertaining to AMI. Several have demonstrated that the clinical sensitivity of cardiac troponin is similar to that of CK-MB during the first 48 hours after the onset of chest pain.[23,56,77,234,239] As an early marker for AMI, cardiac troponin shows a clinical sensitivity of 50% to 65% up to 6 hours after onset of chest pain.[23,44,215,234] Therefore, like CK-MB, cardiac troponin is insufficient for effective early diagnosis. This is exemplified in Figure 44-16 by ROC curve analysis.[44] However, cardiac troponin remains elevated for a much longer time after the onset of AMI (up to 4 to 10 days), giving a high clinical sensitivity (>90%) up to 4 to 7 days after AMI.[56] Clinical specificity calculations for cardiac troponin are dependent on how patients are clinically classified. Specificity will depend on whether patients with minor myocardial injury of nonischemic etiology are included with AMI patients. Typically, because of the highly analytically sensitive nature of second- and third-generation cardiac troponin assays, clinical specificity for cardiac troponin is in the 70% to 85% range.

Brain Natriuretic Peptide

Clinical laboratory testing in the setting of CHF focuses on several goals: (1) to determine the cause of diagnostic symptoms; (2) to estimate the degree of severity of CHF; (3) to estimate the risk of disease progression and risk; and (4) to screen for a less symptomatic disease. Some of the earliest observations compared BNP concentrations in CHF patients with the patient's NYSHA classification. Linear relationships with increasing BNP levels and the severity of CHF have been described for several assays, as represented in Figure 44-17 for BNP and NT-proBNP. However, substantial

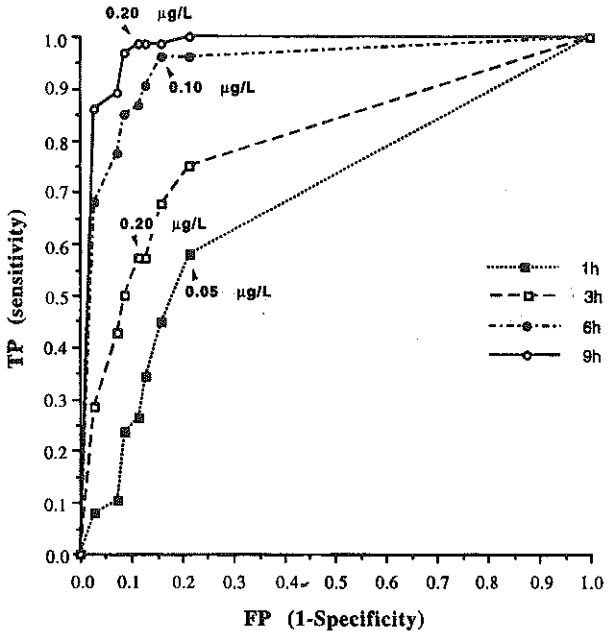

Figure 44-16 Receiver operating characteristic curves to establish the best discriminator limit for cardiac troponin T (cTnT) for predicting AMI. The number of true positives (*y*-axis) and false positives (*x*-axis) are reported in relation to time (h) after the onset of symptoms. The best discriminating point for cTnT is 0.20 µg/L at 9 hours after the onset of chest pain. *(Reprinted by permission of Elsevier Science from Burlina A, Zaninotto M, Secchiero S, Rubin D, Accorsi F. Troponin T as a marker of ischemic myocardial injury. Clin Biochem 1994;27:113-21. Copyright 1993 by Canadian Society of Clinical Chemists.)*

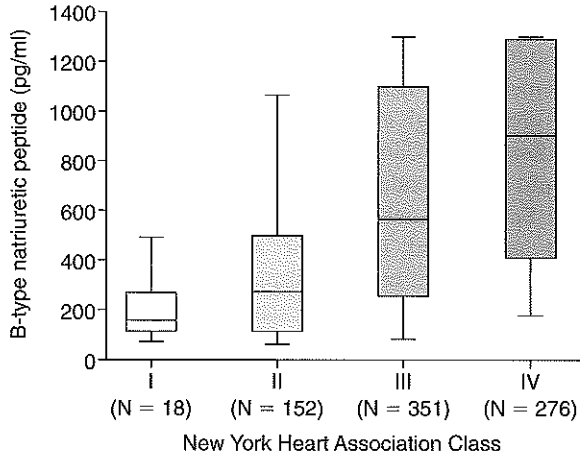

Figure 44-17 Correlation of BNP concentrations (Biosite Triage) according to NYHA classification of heart failure. *(From Maisel AS, Krishnaswamy P, Nowak RM, McCord J, Hollander JE, Duc P, et al. Rapid measurement of B-type natriuretic peptide in the emergency diagnosis of heart failure. N Engl J Med 2002;347: 161-7.)*

differences in BNP and NT-proBNP concentrations are demonstrated in Table 44-8 when comparing NYSHA classes and median BNP and NT-proBNP levels from different clinical studies and assays. Very few studies have directly compared BNP and NT-proBNP measurements. The early studies have focused on the diagnostic role of BNP and NT-proBNP in patients presenting with clinical features of HF. Two large prospective, multicenter trials have evaluated the utility of plasma BNP and NT-proBNP in the initial acute evaluation of patients with CHF.

First, the largest prospective trial to date to evaluate the diagnostic value of BNP is "The Breathing Not Properly Multicenter Study," from which numerous publications have addressed multiple aspects regarding the utility of BNP monitoring.[147,151,152,157,226] In this multinational trial, more than 40% of ED clinicians showed substantial indecision regarding the diagnosis of CHF without the knowledge of BNP. Monitoring BNP was found to be an independent predictor of CHF. Using a blood BNP cutoff concentration of 100 ng/L gave a 90% clinical sensitivity and 75% clinical specificity, with an 81% accuracy. Without BNP monitoring, clinical judgment and traditional diagnostic methods demonstrated a diagnostic accuracy of only 74%. The knowledge of BNP reduced the proportion of patients in whom the clinician was uncertain of the diagnosis from 43% to 11%. These data substantiate early studies that showed that 40% to 50% of clinicians falsely diagnosed CHF in the primary care setting before the advent of BNP.[160] Figure 44-18 shows a CHF diagnosis nomogram and ROC curves that the BNP trial investigators propose to assist in the ED decision making practice, based on pre- and post-BNP testing probabilities for CHF. The second study was a randomized control trial comparing the diagnostic strategy for plasma BNP testing with clinical assessment with BNP (Figure 44-19).[152] Plasma BNP monitoring in the ED improved the treatment and evaluation of patients with early dyspnea, reducing the time to discharge and total cost of treatment. Currently, there is a general consensus that plasma BNP or NT-proBNP testing should be performed (1) to confirm the diagnosis of CHF in patients with a suspected diagnosis of CHF but presenting with ambiguous clinical features or confounding pathology etiologies, such as chronic obstructive pulmonary disease (COPD); (2) as a valuable guide to general, nonspecialist practitioners, to assist and/or improve the diagnostic accuracy for detecting HF; and (3) to assist in ruling out CHF when normal NP concentrations are found. However, other studies have shown that routine plasma BNP or NT-proBNP testing in patients with obvious CHF is not necessary and is not cost effective.[59,75]

The challenge in diagnosing CHF is that many of the presenting symptoms are nonspecific. Yet, studies have shown that there were dramatic differences in BNP of patients with dyspnea caused by cardiac failure (mean of 1076 ng/L) versus BNP in patients with dyspnea caused by noncardiac etiologies (mean of 86 ng/L).[157] ROC curves have shown that BNP had better overall accuracy than the clinician's judgment (AUC 0.97 versus 0.88), with similar findings observed for NT-proBNP.[145] It is important to remember that BNP is "not a stand-alone diagnostic test;" it must be used and

interpreted with regard to the clinical presentation, specifically pertaining to the age and gender of the patient.[59,75]

Use of BNP for Prognosis and Risk Stratification

Results from several studies support the monitoring BNP or NT-proBNP for the risk stratification of patients with CHF, with or without a previous history. This involves patients presenting with a wide range of clinical pathologies, including CHF,[8,49,93a,222] ACS,[63,106,172,190] and noncardiac pathologies such as pulmonary embolism,[125,182] and in a general population screening with no previous history of CHF. In one analysis adjusted for several clinical factors in CHF patients, plasma BNP concentrations were shown to be more closely related to mortality than were symptoms of ejection fraction.

The evidence for risk stratification use for BNP in ACS has recently emerged. As BNP is released by intact cells, including those that are not ischemic, monitoring BNP may, in the future, provide advantages in detecting the pathophysiological consequences of ischemia and cell necrosis (infarction). Studies have demonstrated that increases in BNP concentrations following STE MI were associated with worse left ventricular (LV) systolic function, adverse ventricular remodeling over time, and a greater likelihood of death and CHF.[141,166,170,219] Further, there has been a consistent observation that increased BNP or NT-proBNP measured within the first 5 days after AMI is strongly associated with both short- and long-term risk of cardiac death. For example, BNP was monitored in 220 patients following presentation for AMI and was independently a powerful predictor of left ventricle ejection factor (LVEF), heart failure, or death in the 14-month follow-up. This suggests that BNP correlates with the amount of ventricular dysfunction present after AMI. As previously mentioned, ischemic damage is one of the major etiologies of CHF. Yet, currently it is difficult to identify patients who are at greatest risk of developing CHF following AMI. Having a reliable screening tool to identify patients at highest risk might be the initiating factor in closer follow-up, designed to reduce future morbidity and mortality.

BNP and NT-proBNP concentrations have been found to be increased in ACS patients without LV dysfunction or CHF; and monitoring levels have been demonstrated to provide important prognostic information (Table 44-9). Graded relationships between increasing plasma BNP con-

TABLE 44-9 Studies of BNP and NT-proBNP for Risk Assessment in UA/NSTEMI

Reference	Year	Study	Subjects	Marker	Follow-up	Findings
62	2001	Substudy of RCT (Opus—TIMI 16)	1698	BNP	10 months	RR 12.5 for mortality in highest vs. lowest quartile in NSTEMI, RR 7.9 for mortality in highest vs. lowest quartile in UA
109	2002	Observational	755	NT-proBNP	4 years	RR 26.6 for mortality in highest vs. lowest quartile
172	2002	Observational	405	NT-proBNP	52 months	RR 5.6 for mortality above vs. below median in NSTEMI
173	2002	Substudy of RCT (TIMI 11B)	681	NT-proBNP	6 weeks	Higher baseline biomarker levels in subjects that died (299 pmol/L) than in survivors (138 pmol/L)
159	2003	Substudy of RCT (TACTICS)	1676	BNP	6 months	Increased risk of death at 7 days (2.5% vs. 0.7%) and 6 months (8.4% vs. 1.8%) with BNP > 80 pg/mL
108	2003	Substudy of RCT (FRISC II)	775	NT-proBNP	2 years	RR 4.1 for mortality in highest tertile compared with lowest (invasive), RR 3.5 for mortality in highest tertile compared with lowest (conservative)

centrations and mortality over 6 months have been demonstrated (Figure 44-20), with the OPUS-TIMI 16 trial and TACTICS-TIMI 18 trial providing the largest independent assessment of BNP as a prognostic marker in a complete spectrum of ACS patients.[64] Similar findings have also been described demonstrating that NT-proBNP are strongly associated with risk of mortality.[106,109,172] The use of BNP is synergistic with that of troponin in these patients, and in patients with a normal troponin its use may be particularly helpful. However, at present, there are no therapeutic implications to BNP elevations.

Several studies have evaluated the effects of specific therapies in decreasing the risk associated with BNP and NT-proBNP.* Data from the FRISC II study have shown a greater benefit of an invasive strategy in ACS patients in the highest tertiles of NT-proBNP (Figure 44-21).[108] Of the numerous hormonal markers that have been considered in patients with minimal symptomatic or asymptomatic LV dysfunction, BNP has repeatedly proved most useful in identifying patients with mild, asymptomatic LV dysfunction. In one representative study, only 40% of patients with BNP >56 pg/mL were free of cardiac events during a 3-year follow-up period. In contrast, 90% of those with BNP <56 pg/mL were event free. Comparing BNP levels with other commonly used parameters—such as echocardiography, 6-minute walk test, LVEF, and clinical criteria in 139 CHF patients—multivariate analysis using death as an endpoint demonstrated that BNP independently identified patients with the worst prognosis. Additionally, sustained that BNP increases have been shown to be an independent risk factor for mortality even in the face of improved LVEF and clinical symptoms. Thus, BNP objectively identified patients who were at greatest risk and required more aggressive therapy.

Implications for Therapy

With evidence that monitoring BNP can be helpful in stratifying disease severity, whether treatments that lower BNP result in decreased morbidity and mortality has to be considered, and multicenter studies are underway to address this question. The initial data from smaller trials and pilot studies look promising. A pilot study examined BNP in patients admitted with decompensated CHF and treated with the current standard of care. BNP was monitored regularly during hospitalization (but blinded to physicians) and correlated with the following endpoints: mortality in hospital,

mortality within 30 days after admission, or readmission within 30 days. Patients whose discharge BNP fell below 500 ng/L generally did well. However, increasing BNP during hospitalization with discharge BNP greater than 1000 ng/L strongly correlated to readmission rates or death during 30-day follow-up. In a separate substudy, serial BNP concentrations were compared with changes in hemodynamics for 20 decompensated CHF patients. Patients who were felt to be responding to treatment according to a decrease in wedge pressure (51% change from baseline) experienced a significant drop in BNP compared with nonresponders (55% reduction versus 8% reduction in baseline values). There was a significant correlation between percent change in wedge pressure from baseline per hour and the percent change of BNP from baseline per hour. While outcomes of large trials are pending, BNP appears to be an objective marker that would assess response to treatment and correlate with discharge prognosis.

BNP has also been used for monitoring outpatient therapies.[118,169,189,191,192] Most CHF patients receive the same dose of angiotensin converting enzyme (ACE) inhibitors, because there is currently no objective measure of treatment efficacy. In one representative study, 20 CHF patients were randomized to receive ACE inhibitors titrated according to BNP or to standard treatment protocols for an 8-week period. In the BNP monitored group, there was a significant decrease in mean heart rate and inhibition of the renin-angiotensin-aldosterone system when compared with the empirical therapy group. Only the BNP monitored group showed significant reductions in BNP during the course of therapy. The presumption was that because BNP is a potent predictor of long-term morbidity and mortality, decreasing plasma levels were beneficial. In a similar study addressing NT-proBNP, 69 CHF patients were randomized to titrated therapy (ACE inhibitors, diuretic, and cardiac glycosides) according to plasma NT-proBNP levels or empirical therapy for up to 9 months. Those in the NT-proBNP monitored group had reduced incidence of cardiovascular death, readmission, and new episodes of decompensated CHF. These initial studies suggest that BNP and NT-proBNP are important differential tools for assessing patient status and in tailoring therapy in an outpatient basis, using BNP or NT-proBNP as an important differential tool.

Population-Based Screening

Although echocardiography is the current standard, it is not cost effective enough to be considered as a screening tool. Several studies considered the use of BNP to detect heart disease in the general population and especially those patients considered to be at high risk for CHF.[219,222] A large nonselective population-based survey recently screened more than 1200 primary care patients ages 25 to 74. It was shown that BNP was increased in some patients with asymptomatic left ventricular systolic dysfunction (LVSD). Clinical sensitivity and specificity BNP for identifying LVSD in the whole study population were 77% and 87%, respectively. When detection was restricted to LVSD in participants more than age 55, the area under the ROC curves was 0.85. However, most detection was in those with more severe disease, which often has other clinical correlations. BNP was actually disappointing in patients with mild reductions in LV performance. The accuracy of BNP as a screening tool can be optimized by targeting high-risk individuals. BNP or NT-proBNP is currently not recommended as a screening tool. However, in the Framingham cohort, there was a relationship between tertiles of BNP and long-term cardiac events and mortality even in the absence of elevations.[222]

Two additional clinical entities are worthy of a notation regarding BNP and NT-proBNP. These include obesity and

renal dysfunction. Worldwide, there is an obesity epidemic.[119] Greater numbers of men and women have become obese during the past decade. Few studies have examined the relationships between BNP and NT-proBNP levels in obese patients with and without CHF. For BNP, in patients with CHF, an inverse relationship has been described between increasing body mass index (BMI; obesity) and decreasing BNP concentrations.[161] As of the writing of this chapter, similar data have not been published for NT-proBNP, although it is widely held now that NT-proBNP will manifest the same relationship to BMI as BNP. In non-CHF patients, decreasing BNP and NT-proBNP levels have been shown to correlate with decreasing BMI in conjunction with therapy.[90] The data in regard to NT-proBNP are in contrast to preliminary data that have shown that approximately 15% to 20% of asymptomatic obese patients (BMI >40) have increased NT-proBNP levels.

Regarding renal disease, the largest study to date has shown that CHF is more common in patients with advanced chronic renal disease, with BNP levels independently associated with CHF.[46] At present, however, hemodialysis appears to influence the optimum cutoff concentration for BNP and NT-proBNP in the diagnosis of CHF, with advanced stages of renal disease showing higher cutoff values.[163] BNP and NT-proBNP are secreted in a pulsatile fashion from cardiac ventricles with an approximate half-life for BNP of 22 minutes in blood, with the NT-proBNP half-life on the order of hours. While one mechanism of BNP clearance involves the renal parenchyma, the kidney is not thought to be the primary mechanism for BNP clearance, but likely a mechanism for affecting NT-proBNP clearance. Thus increases in BNP in hemodialysis patients are thought to represent both regulatory responses from the cardiac ventricle, resulting from increased wall tension, and a lack of renal clearance.

Biological Variability

As BNP and NT-proBNP become more widely used to monitor CHF patients following therapy, one investigation has questioned the usefulness of serial monitoring in assisting the success of drug therapy.[231] In this study of 11 patients with CHF, the biological variation for BNP and NT-proBNP was evaluated using four different assays. The findings indicated that a change of 130% for BNP and 90% for NT-proBNP was necessary before results of serially collected data can be considered clinically and statistically significant. For example, these findings imply that a decrease from approximately 500 ng/L to 250 ng/L would be necessary for a clinician to conclude that therapy was successful in improving CHF features. Clinicians without this knowledge may inappropriately assume that a decrease from an admission BNP value of 500 ng/L to a 24-hour postadmission value of 400 ng/L may have been a result of successful patient management. Figure 44-22 shows that in a review of 800 consecutive patients over 3 months, 75% of patients with serial BNP monitoring over 2 to 20 days did not demonstrate >100% variability.[230] These data imply the possibility of a large group of inappropriate BNP orders during the initial several days following admission for managing CHF

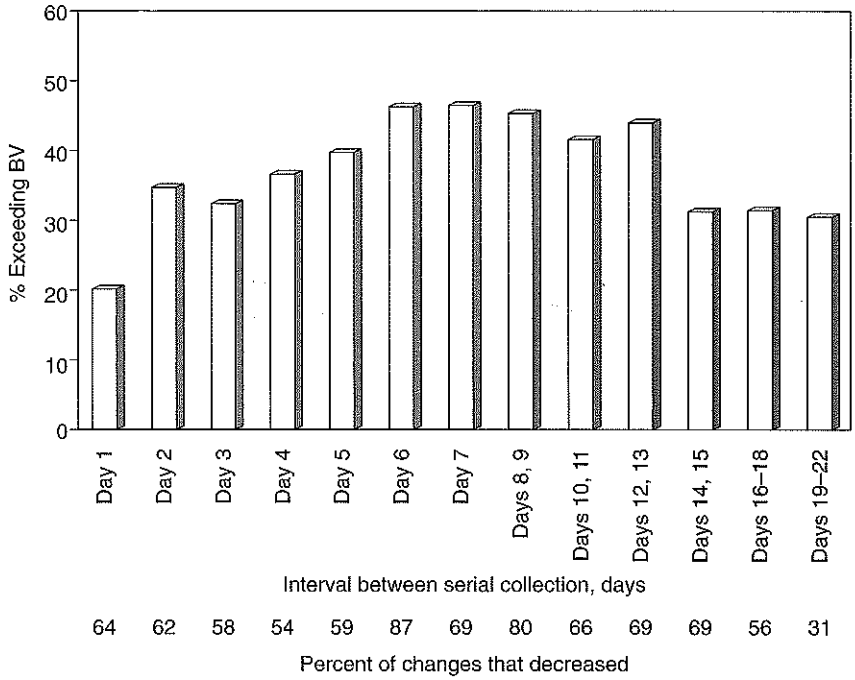

Figure 44-22 Variability of BNP concentrations by day from initial admission order, with demonstration that <50% exceed biological variability (100% change) over a 2-week time period. *(From Wu AHB, Smith A, Apple FS. Optimum blood collection intervals for B-type natriuretic peptide testing in heart failure patients. Am J Cardiol 2004;93:1562-3, with permission from Excerpta Medica.)*

patients. It has been suggested that following the admission BNP value a second BNP value be monitored within 24 hours of discharge to optimize the cost-effective role for BNP in the overall assessment of patients with CHF.

Summary

The ACC/AHA practice guidelines[40] for the evaluation and management of CHF indicate that the role of BNP in the identification of CHF patients remains to be clarified. In contrast, the ESC has incorporated monitoring BNP into their practice algorithm at the time of patient presentation alongside the clinical history, physical examination, ECG, and chest x-ray. An abnormal BNP finding would trigger an echocardiogram or other imaging modality. Several observations have been demonstrated from an overview of the evidence-based literature. First, there is an influence of age and sex in reference groups, with BNP concentrations in patients diagnosed with CHF being substantially increased (>1000 pg/mL for either BNP or NT-proBNP) compared with patients with minor increases (<400 ng/L) because of LV dysfunction without acute CHF. Second, BNP is not 100% specific for CHF. Increases have been described for other non-CHF etiologies involving filling pressure defects, including LV hypertrophy, inflammatory cardiac diseases, systemic arterial hypertension, pulmonary hypertension, acute and chronic renal failure, liver cirrhosis, and several endocrine disorders (e.g., hyperaldosteronism and Cushing's syndrome). Third, in patients with dyspnea secondary to CHF or COPD, BNP concentration is substantially different (mean >1000 ng/L [CHF] and <100 ng/L [non-CHF], respectively). Fourth, in CHF patients presenting to the ED, patients admitted trend to higher BNP concentrations (mean >500 ng/L) versus those who are discharged (mean <300 ng/L) at triage. Fifth, BNP concentrations in patients presenting with edema and in whom CHF is diagnosed trend to higher concentrations (mean >1000 ng/L) compared with non-CHF patients (mean <100 ng/L). Sixth, a survey of patients admitted to the ED with symptoms suggestive of CHF (taken early after the introduction of BNP monitoring at a county medical center) showed that the majority of orders originated from the ED (44%) and cardiology areas (45%).[243] However, after 2 years of clinician experience, there has been a shift towards a higher percentage of use by cardiology services (62%) and general medicine (17%, up from 4%), corresponding with a decrease to 20% in the ED. These findings substantiate a greater, but not necessarily more clinical, appropriate use for patient monitoring and not for diagnostic assistance. Seventh, after an AMI, BNP increases in proportion to the size of the infarction; thus investigators have explored the role of screening BNP for detection of LV dysfunction. Evidence has shown that in post-MI patients, BNP concentrations are inversely correlated with LV ejection fraction. However, there is inconclusive evidence for the role of BNP screening for asymptomatic LV dysfunction in the general population.

On the basis of the current evidence in the literature, we believe that blood BNP monitoring can be valuable in the diagnostic setting, where it will possibly improve the performance of nonspecialist clinicians in diagnosing CHF. In clinical practice, BNP monitoring can best be used as a "rule out" test for suspected cases of new CHF. It should not be a replacement for full clinical assessment, including an echocardiogram when indicated, in the presence of an increased BNP. In the presence of a normal BNP or NT-

proBNP, it is highly unlikely the diagnosis will be CHF when concentrations are <100 ng/L for BNP or <400 for NT-proBNP. Monitoring BNP may be useful in (1) guiding therapy, (2) monitoring the course of the disease, and (3) providing useful risk stratification information. BNP has been shown to be an independent predictor of cardiovascular mortality in patients with both CHF and ACS over a 1-year period. Further, the evidence-based literature suggests that BNP or NT-proBNP monitoring may assist in identifying patients with a lower risk of readmission with the next 30 days before discharge.

CK-2

Although the measurement of CK-2 in serum has been predominantly replaced with cardiac troponin I or T, it is still a useful laboratory test for the diagnosis of AMI and recommended as an acceptable alternative to cardiac troponin.[6] The classic time versus CK-2 level (activity or mass concentration) pattern observed following the onset of chest pain in AMI is shown in Figure 44-23. An initial CK-2 rise takes 4 to 6 hours to increase above the upper reference limit. Peak levels occur at approximately 24 hours. Return to normal (baseline) takes 48 to 72 hours ($t_{1/2}$ of CK-2 is 10 to 12 hours). Factors that might affect the classic pattern include size of infarction, CK-2 composition in the myocardium, concomitant skeletal muscle injury, and reperfusion (spontaneous, following thrombolytics, or following angioplasty). The lack of tissue specificity and differentiation of increased CK-2 caused by the heart or skeletal muscle becomes important, since a normal percentage of CK-2 of total CK activity may be misleading if concomitant injury occurs in skeletal muscle coincident with an AMI. The fractional amount of CK-2 release from the heart would be obscured by the large release of total CK from skeletal muscle injury.

Clinical studies comparing CK-2 mass with activity assays have shown that CK-2 mass measurements provide earlier detection of abnormal CK-2 levels following AMI. Thus clinical sensitivity is improved without sacrificing specificity.[81] Because more than 50% of patients with AMI present to EDs with a nondiagnostic ECG, rapid and sensitive assays for the measurement of CK-2 will help clarify the diagnosis in those patients. In patients admitted to the ED, the clinical sensitivity of a single test (CK-2) result varies considerably based on time after onset of symptoms, with a range of sensitivity from 17% to 62% at 0 hours and from 92% to 100% at 3 hours after presentation.[131] This finding suggests that the traditional serial serum sampling at 0, 12, and 24 hours (which displays the classic rise-and-fall pattern of CK-2 over a 24-hour period) might be replaced with four early serum CK-2 measurements at 0, 3, 6, and 9 hours after presentation.[82]

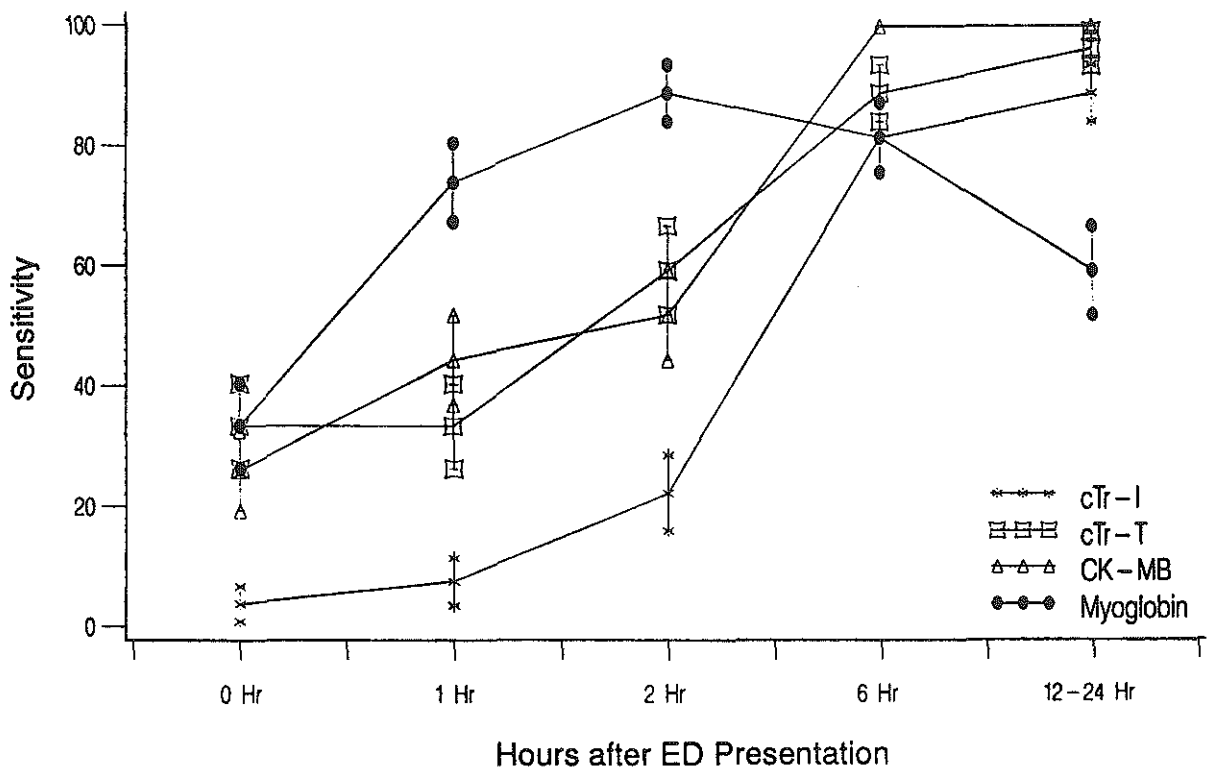

Figure 44-23 Clinical sensitivities (with 95% confidence limits) of creatine kinase-2 (CK-MB), myoglobin, and troponins I and T (cTr-I, cTr-T) for AMI as a function of time from presentation at the emergency department (ED). *(Data from Tucker JF, Collins RA, Anderson AJ, Hauser J, Kalas J, Apple FS. Early diagnostic efficiency of cardiac troponin I and cardiac troponin T for acute myocardial infarction. Acad Emerg Med 1997;4:13-21.)*

As described by the ESC/ACC consensus document on the redefinition of AMI, sampling at a minimum of 6 to 9 hours after presentation is suggested before ruling out AMI.[6] Further, CK-MB mass assays obviate the need for rapid and analytically sensitive assays to examine the small but increasing CK-2 levels in serum during the early hours after the onset of symptoms in AMI patients. The concept that it takes 4 to 6 hours for serum CK-2 levels to become elevated above the upper reference limits was derived from assays that lacked analytical sensitivity and specificity within the reference interval. The improved immunoassays are able to quantitate significant changes during the early hours after the onset of chest pain within the normal range for CK-2 to facilitate earlier AMI detection.

Clinical use of the percent relative index [%RI; %RI – (CK-2 mass/total CK activity × 100) or %CK-2 (CK-2 activity/total CK × 100)] aids in the interpretation of CK-2 concentrations for the detection of AMI. While not absolute, an increased %CK-2 or %RI points toward the heart as the source of CK-2 in serum. However, the %RI and %CK-2 should not be used for interpretation when the total CK activity remains within the reference interval, because of the potential of falsely elevated values.[36] Their use for this purpose is also compromised if there is any concomitant skeletal muscle injury, as the sensitivity for the detection of cardiac events is lost.

Myoglobin

Myoglobin is known for its excellent clinical sensitivity early after MI; however, it has not become a widely used test in clinical or laboratory practice. The majority of clinical and laboratory testing guidelines suggest a possible role for myoglobin for early myocardial detection and early monitoring. However, in general practice, the lack of tissue specificity has been its major obstacle for growth in clinical practice. The major advantage offered by myoglobin as a serum marker for early myocardial injury is that it is released earlier from damaged cells than CK-MB and cardiac troponin, allowing for earlier detection of MI.[80,84] Studies have shown that myoglobin is a very sensitive marker (90% to 100%) for AMI. As shown in Figures 44-12 and 44-23, serum concentrations of myoglobin rise above the reference interval as early as 1 hour after MI, with peak sensitivity in the range of 2 to 12 hours, suggesting that serum myoglobin reflects the early course of myocardial necrosis. Myoglobin is rapidly cleared and thus has a substantially reduced clinical sensitivity after 12 hours. If myoglobin is to have a role in detecting AMI, it must be within the first 0 to 4 hours, the time period in which CK-2 and possibly cardiac troponin are still within their reference intervals. As mentioned earlier, the measurement of serum myoglobin has not been extensively used in clinical laboratories for the routine analysis in AMI, because it has poor clinical specificity (60% to 95%), which is thought to be caused by the large quantities of myoglobin found in skeletal muscle. One attempt to improve clinical specificity involved the monitoring of carbonic anhydrase III (CA III) to assist in differentiating patients with AMI from those with skeletal muscle trauma.[216] After an AMI, serum CA III concentrations remained unchanged, while both CK-2 and myoglobin levels increased. In patients with severe skeletal muscle trauma, serum concentrations of myoglobin, CK-2, and CA III (skeletal muscle–specific) were all elevated. Therefore by using the two serum assays for myoglobin and CA III, it appears possible to distinguish between heart and skeletal muscle injury arising from numerous conditions, such as AMI, open heart surgery, vigorous exercise shock, severe renal failure, and intramuscular injections. However, if both myoglobin and CA III are elevated, one cannot rule out myocardial injury. In 2003, this concept was discussed for clinical implementation.[58] An important use of early serum myoglobin measurements following admission to EDs is their clinical utility as a negative predictor of AMI. For example, if myoglobin concentrations remain unchanged and within the reference interval on multiple, early samplings within 2 to 6 hours after the onset of chest pain, there is almost 100% certainty (99% negative predictive value) that muscle (either cardiac or skeletal) injury has not occurred recently.[80,150]

Lactate Dehydrogenase

LD isoenzymes and total LD activity are no longer measured in clinical practice.[101] For historical perspective, for patients having an AMI, serum total LD values become elevated at 12 to 18 hours after the onset of symptoms, peak at 48 to 72 hours, and return to below the upper reference limit after 6 to 10 days.[227] LD-1 rises within 10 to 12 hours, peaks at 72 to 144 hours, and returns to normal in approximately 10 days after AMI, paralleling total LD. The elevation patterns of LD-1 and total LD contrast with the elevation patterns of total CK and CK-2, which peak at 24 hours and return to below the upper reference limit within 72 hours after the onset of AMI. Because of its prolonged half-life, LD-1 is a clinically sensitive (90%) marker for infarction when used more than 24 hours after occurrence. The LD-1 increase over LD-2 in serum after AMI (the so-called flipped pattern, in which the LD-1/LD-2 ratio becomes ≥1.0) has a clinical sensitivity of about 75% in patients suspected of having sustained an AMI.[72]

GENERAL CLINICAL PRACTICE

While this chapter has reviewed the current recommendation for biomarker testing predicated on cardiac troponin at the 99th percentile or 10% CV limits, different physician groups may adhere to different principles regarding the sensitivity and specificity of a biomarker (cardiac troponin). In emergency medicine, the ED physician desires a test that will provide high specificity and not miss any possible MI patients. However, with the highly improved cardiac troponin assays in the marketplace, the 100% sensitivity that troponin assays offer demonstrates a clinical specificity of

only 65% to 85%, because cardiac troponin detects myocardial injury and not just MI. This is demonstrated in Figure 44-24, which shows ROC curves of patients suggestive of ACS presenting to an inner city hospital to rule in or rule out MI for cTnI[215] and a multicenter evaluation of cTnT for assessing patients with suspected ACS.[56] The timing of serial blood draws will have a substantial influence on the changing sensitivity and specificity calculations. Because cardiac troponin detects any form of myocardial injury, nonischemic mechanisms of injury are also responsible for cardiac troponin release from the heart, causing increases in circulating cardiac troponin. Box 44-1 shows a list of potential etiologies that have been responsible for increases in nonischemic damage to the heart. Thus, whenever cardiac troponin is monitored, it is important to follow the serial pattern of a rising or a falling pattern of the biomarker, as shown in Figures 44-2 and 44-16. An increased cardiac troponin pattern that remains relatively unchanged and is not indicative of this serial trend is likely not an MI.

Strategies for the Role of Cardiac Troponin for Risk Assessment

Patients With Ischemia

In today's environment of preventive and evidence-based medicine, the use of cTnI or cTnT measured once at presentation and again at 12 to 24 hours in patients with ischemia will allow clinicians to use markers as both exclusionary and prognostic indicators. The results will assist in determining who is more at risk for AMI and death, and thereby determine who may benefit from early medical or surgical intervention. An evaluation of the majority of risk stratification studies shows that approximately 30% of all UA and NSTEMI patients present with an increased cardiac troponin level. Of these, approximately 30% (or 9% to 10% overall) have an adverse short-term (30 to 40 days) and long-term (1 to 2 years) prognosis.[93,158,175] Identifying patients at greater risk for cardiac events allows them to be treated more aggressively, with proven beneficial outcomes. There are now data that such patients benefit from the use of low molecular weight heparin, IIB/IIIA platelet antagonists, and an early invasive strategy.[33,88,137] General population screening of hospitalized patients with cTnI or cTnT is not recommended.

Numerous prospective and retrospective clinical studies have evaluated and compared the utility of measurements of cTnI, cTnT, and CK-MB (and myoglobin) for risk stratification or clinical outcomes assessment of ACS patients with possible myocardial ischemia in the ED. These studies included both single test and multitest panel situations. Patients presenting with a complaint of chest pain or other symptoms suggesting ACS have been assigned to blood sampling protocols, including only a single draw at presentation and several serial blood samplings over a 12- to 24-hour period following presentation. A large proportion of this heterogeneous ACS group are patients presenting with UA and NSTEMI. Before the redefinition of AMI by the ESC/ACC consensus document, up to 50% of UA patients progressed to AMI or cardiac death within the first year.

Studies have now demonstrated prognostic similarities between the old classification of UA patients and those with STE AMI. The use of markers is not just simply one of rapidly ruling in or ruling out AMI, but also is important for the medical management of patients with NSTEMI who are undergoing an acute coronary process (high to moderate risk patients). Therefore the goal of monitoring cardiac markers in patients suggestive of ACS with and without AMI would be to identify possible unstable coronary disease and triage to an appropriate therapy regimen. Optimal use of this strategy takes at least two blood samples for cardiac troponin. Assuming an abnormal serum cardiac troponin test is identified, this approach will allow the clinician to offer the patient alternative medical and procedural options. These include: (1) antiplatelet or antithrombic therapies, (2) percutaneous coronary interventional (PCI) procedures, (3) echocardiography, (4) a radionuclide scan, or (5) exercise stress testing to possibly identify the pathological etiology responsible for the tissue release of markers of myocardial injury.

Figure 44-25 summarizes data from a meta-analysis on this subject. Increases in cTnT or cTnI are predictive of adverse outcomes in ACS patients.[93,175] Twenty-one studies were evaluated and odds ratios (ORs) were calculated for both short-term (30 days) and long-term (5 months to 3 years) outcomes (endpoint death or nonfatal MI) in patients with and without ST-segment elevation and in UA patients. Overall, in the approximately 18,000 patients studied, at 30 days the OR for an adverse outcome was 3.4 to 1 for increased troponin. For patients with a positive troponin, the OR to have an adverse outcome in patients with UA was higher (9.3) compared with patients with ST-segment elevation (4.9) for both short- and long-term outcomes.[93] As both cTnT and cTnI offer powerful risk assessment, cardiac troponin monitoring is necessary to include in current practice guidelines—not just regarding diagnosis and management of ACS patients, but as useful risk stratification tool. This approach is supported by the new ESC, ACC, and AHA guidelines. Care must be taken, however, when evaluating individual studies pertaining to prognostic significance, because it is critical to determine the timing of sampling for cardiac marker measurements since results from a single specimen drawn at presentation may conflict with findings based on serial draws over a 24-hour period following presentation. It is recommended to draw two samples (for either cTnI or cTnT; both are not necessary) on ACS patients who do not rule in for AMI—one at presentation and one at ≥6 to 9 hours following presentation. This will allow for an increase in either cardiac troponin to occur above baseline in a patient presenting with a very recent acute coronary lesion. However, it should be noted that a normal cardiac troponin does not remove all risk. It is highly recommended that cardiac troponin results be provided to clinicians within 60 minutes with a preference toward 30 minutes (from the

time blood is drawn to results reported to the physician), using either POCT[89] or central laboratory instrumentation.

For patients with an ischemic mechanism of injury for cardiac troponin increases, prognosis is related in part to the extent of the increase. An estimation of risk is useful in the selection of site of care (CCU, step-down unit, and outpatient setting) and selection of therapy, especially platelet glycoprotein IIb/IIIa inhibitors and coronary revascularization. Several large trials have demonstrated that pharmacological intervention based on an increased cardiac troponin at presentation substantially lowers the risk of death and composite MI or death, in both short- and long-term studies. Figure 44-26[41] is representative of the findings that demonstrate that death or MI is significant for all patients with increased cardiac troponin. A review of numerous trials by the ESC in ACS patient treated with GP IIb/IIIa or enoxaparin has demonstrated cost benefit of treatment and that outcomes improve by incorporating the knowledge of a cardiac troponin monitor into the management algorithm.[33,88,137,138,158] Figure 44-27 shows the reduction in risk associated with therapy in patients presenting with an increased cardiac troponin concentration.

Clinical performance of cardiac troponin assays has been shown to be strongly dependent on the analytical sensitivity and precision of measured concentrations around

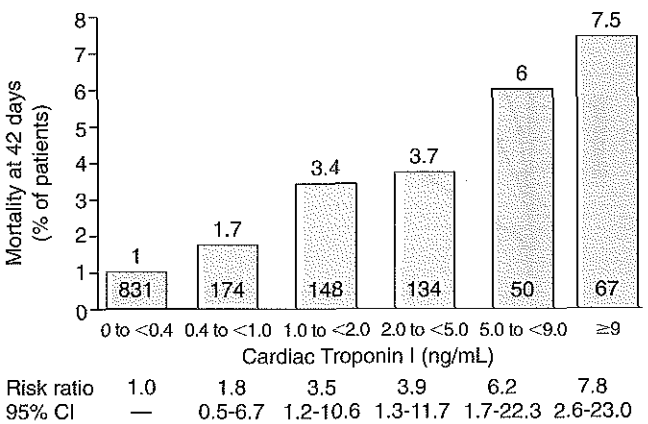

Figure 44-26 Mortality rates at 42 days according to cTnI concentrations measured at enrollment in acute coronary syndrome patients. *(Braunwald E, Antman EM, Beasley JW, Califf RM, Cheitlin MD, Hochman JS, et al. the 99th percentile reference limit and up to the 10% CV cutoff. Several studies have now documented that assays with lower limits of detection are able to identify more ACS patients with poor prognosis who may be candidates for early invasive procedures.[15,220] For example, in one representative study, two assays were compared and used to assess clinical performance in unstable CAD patients.[220] Although both assays showed that patients with normal cTnI levels had a significantly better prognosis than patients with increased levels, a cohort of 11% of patients (n – 98) with a poor prognosis was identified only by the assay with a lower limit of detection. Invasive treatment only reduced clinical events in the group of patients with increased cTnI. Evaluation of a first-generation cTnI assay for risk assessment between the 99th percentile and 10% CV cutoffs also may identify additional patients at risk.[15] Thus each troponin assay, I or T, needs to evaluate the stratification of patients at low-end concentrations to avoid the potential of analytical inaccuracies leading to inappropriate management decisions and therapy.

Patients With Nonischemic Presentations

Since cTnT increases can present over time (8 hours to 10 days), the timing of the myocardial injury index event can be uncertain, especially if the first troponin value is increased. The ESC/ACC consensus document recommends obtaining a CK-MB to assist in clarifying whether the event was recent (i.e., within 46 to 72 hours or later). However, there is no strong evidence to support the added testing with CK-MB. Rather, it is based on the confidence gained from years of experience using CK-MB and the concept that it might be helpful given the persistence of cardiac troponin in the blood. Following the serial rise and/or fall of cardiac troponin should differentiate an early, mid, or late evolving MI from the nonischemic, non-MI patient. For patients undergoing interventional procedures (such as PCI, stents, etc.) increases in cardiac troponin following a normal pre-procedure baseline should be interpreted as indicative of myocardial injury and MI.[6,103]

For patients who undergo cardiac surgery, no cardiac biomarker is capable of differentiating injury caused by acute infarction from the injury associated with the surgical procedure itself. This is true whether CK-MB or cardiac troponin is used as a biomarker. The literature does suggest that higher blood concentrations are likely indicative of a greater amount of injury, irrespective of the mechanism. Because cardiac troponin is cardiac tissue specific (CK-MB is not), monitoring blood cardiac troponin concentrations should be superior to CK-MB. Further, it has been recommended that clinical trials, which have an extensive evidence base predicated on either CK-MB activity or mass, be transitioned toward incorporating cardiac troponin testing.[6,18,40,103,167] Additional studies are necessary for defining the appropriate application of monitoring cardiac troponin for both diagnostic and risk assessment in the cardiac surgery group. This will lend confidence to thoracic surgeons to incorporate the use of cardiac troponins over CK-MB.

Clinicians are often confronted with a clinical history of a patient without overt CAD and a low probability of myocardial ischemia. However, as a precautionary reflex, serial cardiac biomarkers, specifically cardiac troponin, are ordered. When one or two of the serial cardiac troponin concentrations come back increased, the clinician would likely be confronted with the following concerns: (1) What does this increase mean in the clinical setting of a nonischemic patient? (2) Is this a false positive, analytical finding? (3) Why was this test ordered in the first place? As cardiac troponin assays with increasing low-end analytical sensitivity have been developed and marketed, the ability to detect minor degrees of myocardial injury in a variety of clinical conditions has widened and has led to a better understanding that cardiac troponin is not just a biomarker for MI, but a sensitive biomarker for myocardial injury.* The 20% of suspected ACS patients who clinically do not rule in for MI, but display an increased cardiac troponin, represent those nonischemic pathologies in which the mechanisms of injury are well defined (such as myocarditis, blunt chest trauma, and chemotherapeutic agents), along with the unexpected finding of myocardial injury, where these patients have been shown to have increased cardiac troponin, but the mechanism of release is not clear. These observations have led to important and novel investigations involving nonischemic heart disease patients and the role for cardiac troponin as a diagnostic and prognostic tool. The highlighted conditions shown in Box 44-1 demonstrate that in addition to cardiac troponin being indicative of myocardial injury, data also have shown that an increased cardiac troponin is useful as a prognostic tool for assessing risk of death and MI. As an

*References 5, 45, 105, 120, 155, 208, 211, 221.

example (Figure 44-28), pulmonary embolism patients with an increased cTnT >0.1 μg/L were at higher risk of death (44%) during initial hospitalization compared with those with cTnT <0.1 μg/L (3%; $p < 0.001$).[154] This type of observation parallels the risk findings initially observed in ACS patients. There are now strong prognostic data in patients with pulmonary embolism, in patients with CHF, and in and postoperative vascular surgery patients. Elevations presage increased risk. In these situations, the higher the cardiac troponin, the greater the risk.

End Stage Renal Disease

Patients with end stage renal disease (ESRD) have been a subset of nonischemic patient in which risk stratification is also found based on cardiac troponin monitoring. The prevalence of increased cTnT has been shown to be greater than cTnI in these patients.[14] For example, several studies have demonstrated that increases in cTnT and cTnI in ESRD patients show a twofold to fivefold increase in mortality over 2 to 3 years, with a greater number of patients having an increased cTnT.[14,66] The largest clinical study reported to date (Table 44-10) shows that the risk stratification for death by baseline cTnT and cTnI concentration over 3 years follow-up is influenced by the cutoff concentration (ROC, 10% CV, 99th percentile) used. Increased versus normal cTnT was predictive of increased mortality using all three cutoffs for cTnT but only above the 99th percentile for cTnI. Figure 44-29 shows the respective Kaplan Meier survival curves by baseline troponin cutoffs for cTnT and cTnI. Adjusted relative risks of death associated with elevated (>99th percentile) cTnT were 3.9 for cTnT and 2.0 for cTnI. These findings may provide helpful information for decision making for the cardiologist, but may have even more of an impact on risk stratification for the nephrologist. The most important part of the evaluation is to rule out ACS. The data are similar for patients with or without renal dysfunction.[30] Any elevation of cardiac troponin is associated with increased risk. Once the presence of ACS is excluded, then attempts can be made to determine if blood pressure control, volume status, and metabolic status are optimal since it is likely they contribute to the ongoing myocardial injury. In one study, an association was found between LVH and an elevated cardiac troponin with a marked increase in risk.[66] Unfortunately, appropriate therapeutic modalities have not yet been established to address management decisions based on increased cardiac troponin values. The mechanisms responsible for the unexplained differences in elevations between cTnT and cTnI remained unexplained.[14,67,69]

RR, Relative risk.

*Adjusted for age, predraw history of coronary artery disease, and time since initial hemodialysis (<1 year, 1 to 5 years, >5 years); the number of the 733 patients with an increased troponin by cutoff (μg/L): cTnT ≥0.01, n = 601; cTnI ≥0.10, n = 45.

Clinical Utility of Cardiac Markers in Monitoring Reperfusion Following Thrombolytic Therapy

Elevations in cTnI and cTnT are highly specific for myocardial injury. However, in individuals without myocardial disease, their levels are very low to undetectable. This is in contrast to the low but measurable concentrations of CK-2 and myoglobin detected in serum from skeletal muscle turnover in patients with noncardiac-related diseases and in normal individuals. Therefore release of cTnI or cTnT from myocardium into the blood following AMI and after the washout that accompanies successful reperfusion generates an excellent signal compared with no detectable baseline levels before myocardial damage. The initial rapid release of cardiac troponin subunits I and T following successful reperfusion is most likely derived from the soluble cytosolic myocardial fraction (6% cTnT; 3% cTnI).

When an STE AMI occurs, there is a thrombus responsible for the occlusion. It can be lysed by the administration of thrombolytic agents or pushed downstream with primary angioplasty. However, this often occurs long after the anoxic myocardial tissue is irreversibly damaged. Thus to be optimally effective, reperfusion must be initiated as soon after the onset of symptoms as possible.[78]

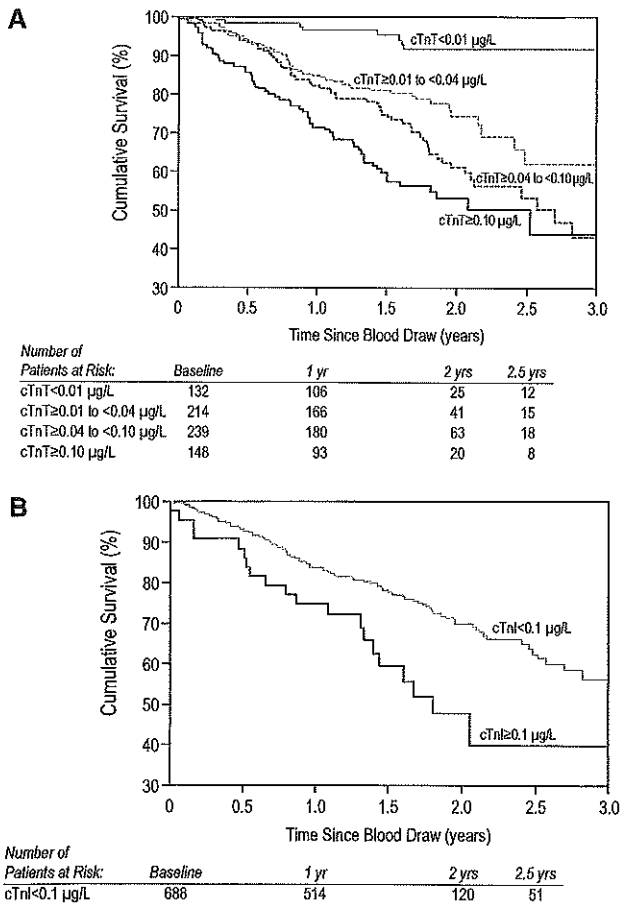

Figure 44-29 Kaplan Meier survival curves by baseline cardiac troponin cutoffs. *(From Apple FS, Murakami MM, Pearce LA, Herzog CA, et al. Predictive value of cardiac troponin I and T for subsequent death in end-stage renal disease. Circulation 2002;106:2941-5.)*

Unfortunately, reperfusion can cause tissue damage, a syndrome known as reperfusion-ischemic injury.[223] This syndrome comprises (1) membrane and microvascular damage, (2) arrhythmias, (3) myocardial stunning, (4) cell necrosis, and (5) hemorrhage. Ischemia quickly causes depletion of intracellular high-energy phosphates, such as ATP and ADP, in the endothelial cells lining the cardiac vasculature. The resulting intracellular acidosis inactivates the membrane ion pumps, causing an influx of calcium ions, which activates intracellular phospholipases, causing membrane structure disruption. Membrane disruption also permits loss of protective free radical-scavenging enzymes, such as superoxide dismutase, glutathione peroxidase, and catalase. When reperfusion occurs, the damaged endothelium attracts activated polymorphonuclear leukocytes (neutrophils) that produce oxygen free radicals that are less effectively scavenged, because of the earlier loss of the scavenging enzymes from the disrupted endothelium. The neutrophils also secrete proteases that cause microvascular damage. The membrane damage alters the cellular action potentials, resulting in cardiac arrhythmias, although these can be controlled with drug therapy. In addition, it may cause myocardial stunning and prolonged LV dysfunction after reperfusion. Thus reperfusion may increase cell necrosis. Whether this is caused by the acceleration of the death of cells already dying or by the action of free radicals killing previously healthy cells is not clear. Finally, as might be expected, the use of thrombolytic agents poses a distinct possibility of hemorrhage. Indeed the use of such agents is absolutely contraindicated in patients with evidence of recent active bleeding.

The clinical utility of cardiac biomarkers for monitoring reperfusion following thrombolytic therapy has not gained favor as a routine form of testing for determining the success or failure of reperfusion therapy.[20,27,74,116,237] It is accepted that the kinetics of myocardial protein appearance in the circulation depends on infarct perfusion. Early reperfusion causes an earlier increase above the upper reference limit and an earlier and greater enzyme peak after reperfusion. However, once the peak has occurred, there is no difference in the time of clearance of enzymes. In addition, enhanced washout identifies whether an artery is patent or closed, but cannot distinguish between normal and abnormal coronary perfusion, which is a key prognostic parameter. Further, it is difficult to assess the amount of irreversible myocardial injury by infarct sizing because of the large variability in the amount of enzyme washout that appears after reperfusion.

In practice, the laboratory becomes involved if a serum test is available as an early marker to assess successful reperfusion after AMI. With early, frequent serum sampling, it may be possible to use the rate of increase in a cardiac biomarker (cTnI, cTnT, myoglobin, and CK-2) concentration to

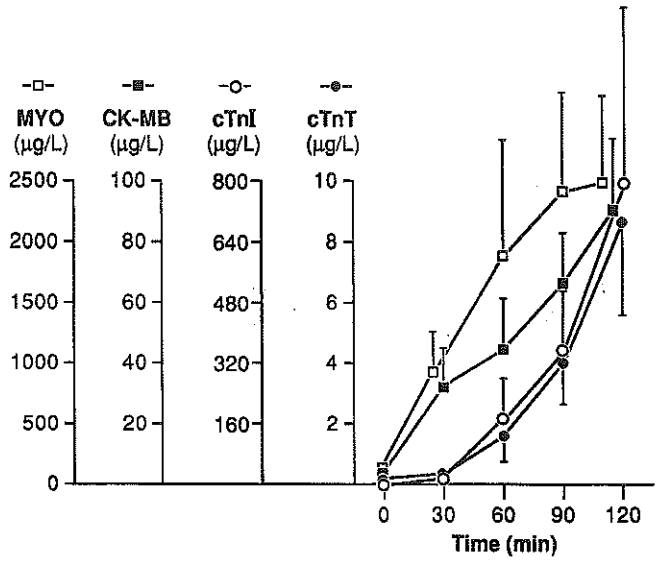

Figure 44-30 Time course (mean and standard error) of serum cardiac troponin I (cTnI), cardiac troponin T (cTnT), creatine kinase-2 (CK-MB), and myoglobin (MYO) concentrations after initiation of thrombolytic therapy in patients with TIMI Grade 3 reperfusion flow. *(From Apple FS, Sharkey SW, Henry TD. Early serum cardiac troponin I and T concentrations following successful thrombolysis for acute myocardial infarction. Clin Chem 1995;41:1197-8.)*

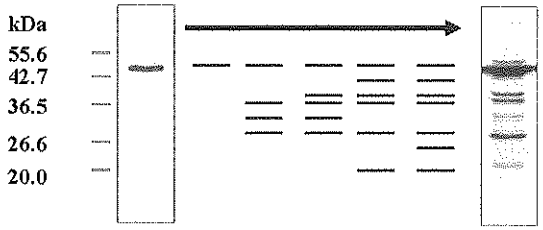

Figure 44-31 Proteomics of different disease phenotypes of cardiac troponin I associated with progression of disease. Each unique stage-specific protein change will, if detected in serum, allow disease stratification. *(Adapted courtesy J.Van Eyk.)*

determine the presence or absence of reperfusion following thrombolytic therapy as early as 30 minutes to 3 hours after the onset of chest pain in AMI. Several studies have demonstrated that (1) following thrombolytic therapy in AMI patients, greater than twofold increases in biomarkers occur within 90 minutes of reperfusion; (2) the rate of increase of biomarkers within the first 4 hours separates reperfused from nonreperfused patients; and (3) after myocardial reperfusion in AMI patients, washout of all biomarkers parallels each other (Figure 44-30). But even in this situation, a distinction between TIMI 3 (normal) and TIMI 2 (abnormal) flow is not possible.

Use of Multimarkers

There is a growing body of evidence regarding that different cardiac biomarkers provide independent and complementary information about pathophysiology, diagnostics, prognostics, and response to therapy in ACS patients. Thus it is probable that multimarker strategies or biochemical profiling may be used to characterize individual patients presenting with ACS. Two representative studies will be addressed. For example, using binary cutoffs for cTnI, BNP, and hsCRP, Sabatine et al have demonstrated 30-day mortality increases in ACS patients of twofold for one marker, fivefold for two markers, and thirteenfold for all three biomarkers.[198] In the Checkmate multicenter study,[168] a POCT system that measured cTnI, CK-MB, and myoglobin multimarker analysis identified positive patients earlier and provided a better risk stratification for 30-day mortality than the central laboratory analysis of CK-MB alone (20% versus 3%, respectively). The multimarker strategy in this study, however, was not designed for diagnostic rule in or rule out information. The addition of myoglobin to cTnI and CK-MB added one additional patient at risk for death at 30 days out of 1005 patients. Unfortunately the multimarker POCT cutoffs used were significantly lower (99th percentile) than the central laboratory assays (ROC curve) cutoff.

Figure 44-31 is a schematic that demonstrates that future proteomic research may allow for the detection of a single cTnI form (indicating recent injury) to multiple forms (indicating an older injury), thus potentially assisting in both the timing of an MI and the determination of the etiology of the injury to the myocardium.[127]

Estimation of Infarct Size

Prior studies have demonstrated the use of the integrated values for total and/or CK-MB to estimate the biochemical extent of infarction.[149,186,195] Further studies verified that the amount of cardiac damage is the primary determinant of prognosis.[71,174,205] Such determinations have been correlated with morphological infarct size. Some have used the peak CK-MB value as a surrogate for the integrated data. Reperfusion changes the release ratio (the percentage of marker that appears in the blood relative to the amount depleted from myocardium), making infarct sizing problematic in the modern era. Some, after fairly comprehensive animal experiments, have claimed that the integrated values or the 72-hour value for HBD (LD-1 and LD-2) can be used regardless of whether reperfusion occurs or not. However, there is substantial LD1 and 2 in red blood cells so that bleeding, either systemically or into the area of infarction, can lead to spurious increases in apparent infarct size. Furthermore, to date, this approach has not been compared with pathological measurements. Both experimental and patient-related data have suggested that the 72-hour troponin measurement correlates with scintigraphically determined infarct size. The data are stronger for troponin T than for I although the principles are probably similar for both analytes.

CHAPTER 45

Kidney Disease*

Michael P. Delaney, B.Sc., M.D., M.R.C.P., Christopher P. Price, Ph.D., David J. Newman, Ph.D., and Edmund Lamb, Ph.D.

The kidneys play a central role in the homeostatic mechanisms of the human body, and reduced renal function strongly correlates with increasing morbidity and mortality. Biochemical investigations, both routine and specialized, are an important part of the clinician's diagnostic armamentarium, and investigations from the nephrology wards and clinics constitute a significant element of the workload of most laboratories. The aim of this chapter is to ensure that the clinical chemist/biochemist understands the perspective of the nephrologist when dealing with laboratory investigations for patients with kidney disease. The basic anatomy and physiology of the kidneys are described as a foundation to understanding the pathophysiology of disease and the rationale for diagnostic and management strategies in kidney disease. The key analytical methods employed during the investigation of kidney disease are dealt with in Chapter 24.

ANATOMY

The kidneys form a paired organ system located in the retroperitoneal space. They extend from the level of the lower part of the 11th thoracic vertebra to the upper portion of the 3rd lumbar vertebra, with the right kidney situated slightly lower than the left. The adult kidney is about 12 cm long and weighs about 150 g in men and 135 g in women (Figure 45-1).[251] In the majority of cases, each kidney receives its blood supply from a single renal artery derived from the abdominal aorta, with the venous return along a renal vein that emerges into the vena cava. However, multiple renal arteries occur in anatomical dissection studies in 30% of cases and following angiography multiple renal arteries are observed in 20% to 27% of patients.[34]

The kidneys have both sympathetic and parasympathetic nerve supplies whose function appears to be predominantly associated with vasomotor activity. The renal lymphatic drainage includes fine lymphatics in the glomerulus, some in close proximity to the juxtaglomerular apparatus, which are associated with removal of material from the glomerular mesangial cells.[428]

Blood Supply

The renal artery divides into posterior and anterior elements, which then divide into interlobar, arcuate, interlobular, and ultimately into the afferent arterioles, which expand into the highly specialized capillary beds that form the glomerulus (Figure 45-2). These capillaries then rejoin to form the efferent arteriole that then forms the capillary plexuses and the elongated vessels (the *vasa recta*) that pass around the remaining parts of the nephron, the proximal and distal tubules, the loop of Henle, and the collecting duct, providing oxygen and nutrients and removing ions, molecules, and water, which are reabsorbed by the nephron. The efferent arteriole then merges with renal venules to form the renal veins, which emerge into the inferior vena cava.[251] The complex architecture of the intrarenal vascular tree is ordered in three dimensions in a characteristic arrangement that probably serves to distribute the blood pressure and flow appropriately to the glomeruli.

In adults, the kidneys receive approximately 25% of the cardiac output, about 90% of which supplies the renal

*This chapter is dedicated to the memory of our friend and colleague Dr. David Newman, who died during its preparation.
